The lesions were composed of perifollicular granulomas consisting of lymphocytes, plasma cells, histiocytes, epithelioid cells, some neutrophils, and numerous foreign body giant cells.²⁶⁰ In one case, the granulomas developed around a nonruptured epidermoid cyst.²⁵⁹ Foreign body giant cells would be unusual as the predominant feature in rosacea; accordingly, this etiological theory (discussed previously) seems unlikely.

PERIORAL DERMATITIS

Perioral dermatitis is regarded by some as a distinct entity²⁶⁴ and by others as a variant of rosacea.²⁶⁵ The histological changes seen in perioral dermatitis and acne rosacea overlap, and clinical features are often more important in separating these two conditions.²⁶⁶

Red papules, papulovesicles, or papulopustules on a background of erythema are arranged symmetrically on the chin and nasolabial folds with a characteristic clear zone around the lips.²⁶⁷ Lesions may occur less commonly on the lower aspect of the cheeks and on the forehead.²⁶⁸ A periocular variant has also been described.^{269,270} Perioral dermatitis mainly affects young women, but it has also been reported in children.^{271–274} In a review of patients with lip and perioral area dermatitis, Nedorost presented a useful table with the distinguishing features between a rosacea-type of perioral dermatitis, a steroid-induced type, and disease due to irritants, allergic/photoallergic contact reactions, and atopic cheilitis.²⁷⁵ She suggests that an extended patch test series may be useful in making a diagnosis.²⁷⁵ Inhaled corticosteroids may also induce the disease.²⁷⁶

Granulomatous perioral dermatitis of childhood is particularly seen in children of Afro-Caribbean descent. This form has been given the acronym FACE – facial Afro-Caribbean childhood eruption.^{277–279} This term is no longer used because of its rare occurrence in non-black children. The term **childhood granulomatous periorificial dermatitis** is now preferred.^{280,281} Subtle clinical differences exist between this condition and perioral dermatitis and granulomatous rosacea, although it may still be a variant of one of these conditions. It has also been proposed as a childhood variant of lupus miliaris disseminatus faciei (see later).²⁸² It is benign, self-limited, and typically resolves within a year of onset without scarring.²⁸⁰ Extrafacial lesions may occur.^{280,283} Its resolution seems to be hastened with the use of systemic antibiotics²⁸³ or with tacrolimus.²⁸⁴

In many cases, perioral dermatitis appears to be related to the application of one or more cosmetic preparations that may act by occlusion.²⁸⁵ The use of strong topical corticosteroids, particularly fluorinated ones, may also have an etiological role.^{286–288} Recent cases have been related to the use of inhaled corticosteroids²⁸⁹ or an intranasal corticosteroid spray.²⁹⁰ Various types of toothpaste have been implicated.^{291,292} Perioral dermatitis has been reported in renal transplant recipients maintained on oral corticosteroids and azathioprine.²⁹³ It has also been associated with the wearing of the veil by Arab women.²⁹⁴

Its relative rarity in patients with seborrheic dermatitis treated with corticosteroids has led to the postulate that perioral dermatitis may develop under fusiform bacteria-rich conditions rather than *Malassezia*-rich conditions as in the case of seborrheic dermatitis.²⁹⁵

Topical metronidazole, erythromycin, and oral tetracyclines have been used as conventional treatments. Liquid nitrogen, benzoyl peroxide, and oral isotretinoin are other therapies. Three cases reported from Japan were successfully treated with a β -lactam antibiotic, cefcapene; fusobacteria were detected prior to treatment using a tape stripping method and were negative following completion of treatment.²⁹⁶ Topical pimecrolimus has been used successfully.²⁹⁷ Its efficacy was confirmed by a randomized, vehicle-controlled study of 1% pimecrolimus cream. It was found to rapidly improve clinical symptoms, being most effective in corticosteroid-induced perioral dermatitis.²⁹⁸

Histopathology

The histological changes in perioral dermatitis have been described as identical to those seen in rosacea.^{265,271} Others have found the epidermal changes to be more prominent than in rosacea, consisting of parakeratosis, often related to hair follicle ostia, spongiosis, which sometimes involves the hair follicle, and slight acanthosis.²⁹⁹ The changes in the dermis are similar to those in papular rosacea and consist of perivascular or perifollicular infiltrates of lymphocytes and histiocytes and vascular ectasia. Uncommonly, an acute folliculitis is present. Tuberculoid granulomas have been described in the dermis in some series but not in others.^{299,300}

In childhood granulomatous periorificial dermatitis, epithelioid granulomas are often perifollicular in distribution. This is not a feature of sarcoidosis.²⁸⁰ Furthermore, the granulomas are more tuberculoid than sarcoidal in type.

LUPUS MILIARIS DISSEMINATUS FACIEI

Although the cause of lupus miliaris disseminatus faciei is unknown, it may be related to rosacea.^{301,302} It has also been called acne agminata and acnitis.³⁰³ It is characterized by yellowish brown papules distributed over the central part of the face, including the eyebrows and eyelids. When widespread facial lesions are present, the appearances may mimic sarcoidosis.³⁰⁴ Occasionally, lesions occur elsewhere, including the axillae.^{305,306} The lesions last for months and heal with scarring.³⁰⁷ This condition occurs in both sexes, predominantly in adolescents and young adults and rarely in the elderly.^{308,309} It has been suggested that because the currently used name is confusing, a new title should be substituted – **FIGURE (facial idiopathic granulomas with regressive evolution)**.³¹⁰

Studies using PCR techniques have failed to demonstrate the DNA of *M. tuberculosis* in lesional skin.³¹¹

Successful treatment with the 1450-nm diode laser has been reported.³¹²

Histopathology

There are few histopathological studies of this condition.³¹³ Biopsy appearances overlap those of both rosacea and perioral dermatitis. The characteristic lesion is an area of dermal necrosis, sometimes described as caseation necrosis, surrounded by epithelioid histiocytes, multinucleate giant cells, and lymphocytes (**Figs. 7.6A and 7.6B**). In many cases, granulomas appear related to ruptured pilosebaceous units.³¹⁴ In one example from our files, caseation necrosis partly involved a ruptured follicle and was, in turn, surrounded by a palisade of epithelioid histiocytes. Nuclear fragments may be seen in the necrotic foci. Early lesions show superficial perivascular infiltrates of lymphocytes, histiocytes, and occasional neutrophils. Late lesions have these changes together with dermal fibrosis, particularly about follicles. Established lesions may show tuberculoid or suppurative granulomas. *Demodex folliculorum* were not seen in one study.³¹³ Small vessel changes with necrosis of blood vessel walls, thrombi, and extravasated red blood cells have also been described.³⁰⁵

One study of lysozyme in these lesions suggests that there is an immunological mechanism involved in the pathogenesis of this condition rather than a foreign body reaction to an unidentified dermal agent.³¹⁵ Conversely, it has been suggested that the lesions represent a granulomatous reaction to damaged pilosebaceous units.³¹⁶

Differential diagnosis

Those examples showing ‘caseous’ necrosis are relatively specific for lupus miliaris disseminatus faciei, given the clinical context of the lesions and their relationship to hair follicles. In this author’s view, lesions that show only perifollicular granulomas without caseation

Figure 7.6 Lupus miliaris disseminatus faciei. (A) A shave biopsy of one of several papules near the lower eyelid. (B) This lesion demonstrates significant caseation necrosis. (H&E)

cannot be reliably distinguished from granulomatous rosacea or perioral/periorbital dermatitis and probably should not be considered diagnostic of lupus miliaris, unless other sampled lesions from the same individual show typical caseating granulomas. There is a resemblance to the palisading necrobiotic form of *granuloma annulare*, but the necrobiotic material in the latter is distinctly mucinous, and a relationship to a hair follicle is generally not observed in granuloma annulare. Despite the similarities to granulomatous *tuberculosis* with caseous necrosis, special stains are negative for acid-fast organisms in lupus miliaris. The tuberculoid granulomas of this condition differ from the naked tubercles of *sarcoidosis*, which do not display this type of necrobiosis but instead only occasionally display small foci of fibrinous material within granulomas; in addition, sarcoidosis can be excluded on the basis of other clinical and laboratory data.

CROHN'S DISEASE

Noncaseating granulomas of tuberculoid type may be found, rarely, in the dermis and subcutis in Crohn's disease (see p. 572). The term metastatic Crohn's disease is often used for the presence of multiple cutaneous lesions.³¹⁷ Granulomas are not uncommon in the wall of perianal sinuses and fistulas. A granulomatous cheilitis has also been

reported (see p. 210).³¹⁸ It is important to exclude Crohn's disease in cases of apparent Melkersson–Rosenthal syndrome.³¹⁹

There is a report of cutaneous granulomas developing in a patient with histologically proven ulcerative colitis.³²⁰

NECROBIOTIC (COLLAGENOLYTIC) GRANULOMAS

The term 'necrobiosis' has been retained here because of common usage and refers to areas of altered dermal connective tissue in which, by light microscopy, there is blurring and loss of definition of collagen bundles, sometimes separation of fibers, a decrease in connective tissue nuclei, and an alteration in staining by routine histological stains, often with increased basophilia or eosinophilia. The term 'collagenolytic' granuloma is favored by others.³²¹ Granular stringy mucin is sometimes seen in such areas in granuloma annulare, and fibrin may be seen in rheumatoid nodules. Necrobiotic areas are partially or completely surrounded by a histiocytic rim that may include multinucleate giant cells. In some cases, histiocytes become more spindle-shaped and form a 'palisade'.

Necrobiotic (collagenolytic) granulomas³²² are found in the following conditions:

- Granuloma annulare and its variants
- Necrobiosis lipoidica
- Necrobiotic xanthogranuloma
- Rheumatoid nodules
- Rheumatic fever nodules
- Reactions to foreign materials and vaccines
- Miscellaneous diseases.

GRANULOMA ANNULARE

Granuloma annulare is a dermatosis, usually self-limited, of unknown etiology and characterized by necrobiotic (collagenolytic) dermal papules that often assume an annular configuration.³²³ The skin or the subcutis or both may be involved. The clinical variants of granuloma annulare include localized, generalized, perforating,³²⁴ and subcutaneous or deep forms.^{325,326} Rare types include a follicular pustulous variant,³²⁷ an acute-onset, painful acral form,³²⁸ and a patch form,³²⁹ although the latter cases are probably examples of the interstitial granulomatous form of drug reaction (see p. 216). The linear variant reported some years ago would now be regarded as a variant of interstitial granulomatous dermatitis (see p. 214).³³⁰ Classic granuloma annulare was preceded in one case by the development of a severe linear form along Blaschko's lines.³³¹

In the *localized* form, one or more erythematous or skin-colored papules are found. Grouped papules tend to form annular or arciform plaques. The hands, feet, arms, and legs are the sites of predilection in approximately 80% of cases.³³² A papular umbilicated form has been described in children in which grouped umbilicated flesh-colored papules are limited to the dorsum of the hands and fingers.³³³ The *generalized* form accounts for approximately 15% of cases.^{323,334} Multiple macules, papules, or nodules are distributed over the trunk and limbs.³³⁵ Rarely, there may be confluent erythematous patches or plaques.^{336,337} The appearances may even simulate mycosis fungoides.³³⁸ It has been reported as a side effect of allopurinol,³³⁹ amlodipine,³⁴⁰ and TNF- α inhibitors;³⁴¹ the latter finding is somewhat contradictory in that TNF- α inhibitors have been used successfully as treatment of this form of the disease.^{342–345} Lesions in *perforating granuloma annulare* are grouped papules, some of which have a central umbilication with scale.³⁴⁶ The extremities are the most common site. The

generalized form may also have perforating lesions.³⁴⁷⁻³⁴⁹ A high incidence of perforating granuloma annulare has been reported in Hawaii.³⁵⁰ It is rare in infants and young children.³⁵¹ In *subcutaneous (or deep) granuloma annulare*, deep dermal or subcutaneous nodules are found on the lower legs, hands, head, and buttocks.^{352,353} These lesions are associated with superficial papules in 25% of cases.³⁵⁴ This group also includes those lesions described as pseudorheumatoid nodules, palisading subcutaneous granuloma, and benign rheumatoid nodules.³⁵⁵⁻³⁵⁷ Although arthritis does not usually occur in children with these nodular lesions, IgM rheumatoid factor has been found in serum in some cases.^{358,359} There is a report of one case occurring in association with juvenile rheumatoid arthritis.³⁵⁷ Computed tomography (CT) scan changes of this variant have been described.³⁶⁰ Rarely, the changes may involve deeper soft tissues and produce a destructive arthritis and limb deformity.³⁶¹ Pseudorheumatoid nodules have also been reported in adults. A series of 14 cases all involved females, and most involved the small joints of the hand.³⁶² Granuloma annulare was present at the periphery of the nodules in 8 cases.³⁶² The authors suggested the term juxta-articular nodular granuloma annulare for these cases.³⁶²

Granuloma annulare has been reported as a seasonal eruption on the elbows or hands^{363,364} and from unusual sites such as the penis,³⁶⁵⁻³⁶⁸ palms,³⁶⁹ about the eyes,³⁷⁰⁻³⁷³ and ear.^{374,375} There has been one case of cutaneous granuloma annulare associated with histologically similar intra-abdominal visceral lesions in a male with insulin-dependent diabetes.³⁷⁶

Females are affected more than twice as commonly as males. The localized and deep forms are more common in children and young adults.^{353,377} The deep (subcutaneous) form has been reported as a congenital lesion.³⁷⁸ Generalized granuloma annulare occurs most frequently in middle-aged to elderly adults. Most cases of granuloma annulare are sporadic, but familial cases have occasionally been reported.³⁷⁹ Patients with the generalized form of the disease show a significantly higher frequency of HLA-BW35 compared with controls and with those who have the localized form of the disease.³⁸⁰

Lesions of granuloma annulare have a tendency to regress spontaneously; however, approximately 40% of cases recur.³⁸² Resolution of lesions subject to biopsy, but not other lesions, has been reported.³⁸¹ In one series, spontaneous regression of localized lesions in children occurred from 6 months to 7 years, with a mean of 2.5 years.³⁸² In the generalized form, the clinical course is chronic with infrequent spontaneous resolution and poor response to therapy.³⁸⁵ Nonperforating lesions are usually asymptomatic.³⁸³

Although the etiology and pathogenesis of the skin lesions in granuloma annulare remain uncertain, possible triggering events include insect bites, trauma, the presence of viral warts, drugs, erythema multiforme, and exposure to sunlight.^{340,384-386} Lesions have occurred in the scars of herpes zoster, localized or generalized,³⁸⁷⁻³⁹³ in a saphenectomy scar,³⁹⁴ in a Becker's nevus,³⁹⁵ and at the sites of tuberculin skin tests.³⁹⁶ The possible link between both the localized and generalized forms and diabetes mellitus remains controversial. There is more convincing evidence of this association with the generalized form than with the localized form, although there may be a weak association with nodular as opposed to the annular type of localized lesion.³⁹⁷⁻³⁹⁹ Significantly lower serum insulin levels have been found in children with multiple lesions of granuloma annulare.⁴⁰⁰ One study of two children with diabetes mellitus documented early, transient development of granuloma annulare, followed by the later development of persistent necrobiosis lipidica.⁴⁰¹ A case-control study failed to find any association between granuloma annulare and type 2 diabetes mellitus.⁴⁰² Reported cases of the concurrence of these two diseases may represent the chance association of two not uncommon conditions.⁴⁰³ It has been reported in association with necrobiosis lipidica,⁴⁰⁴ sarcoidosis,¹⁹⁸ scabies,⁴⁰⁵ Alagille syndrome,⁴⁰⁶ toxic adenoma of the thyroid,⁴⁰⁷ autoimmune thyroiditis,^{408,409} uveitis,⁴¹⁰ hepatitis B⁴¹¹ and C infection,⁴¹²

photoinduction by paroxetine,⁴¹³ during treatment of hepatitis C infection with pegylated IFN- α ,⁴¹⁴ Epstein-Barr virus infection,^{415,416} parvovirus B19 infection,⁴¹⁷ BCG⁴¹⁸ (including generalized granuloma annulare),^{419,420} hepatitis B,⁴²¹ and antitetanus vaccination,^{422,423} waxing-induced pseudofolliculitis,⁴²⁴ tuberculosis,^{425,426} tattoos,^{427,428} granulomatous⁴²⁹ and patch-stage⁴³⁰ mycosis fungoides, a monoclonal gammopathy,⁴³¹ hypercalcemia,⁴³² myelodysplastic syndrome,⁴³³ chronic myelomonocytic leukemia,⁴³⁴ Hodgkin's lymphoma, non-Hodgkin's lymphoma, including cutaneous marginal zone lymphoma,⁴³⁵ gastrointestinal stromal tumor,⁴³⁶ and metastatic adenocarcinoma.⁴³⁷⁻⁴⁴⁶ In these conditions, the clinical presentation may be atypical.⁴⁴⁷ Localized, generalized, and perforating forms of granuloma annulare have been reported in patients with AIDS; the generalized form is the most common clinical pattern.⁴⁴⁸⁻⁴⁵⁸ It may, rarely, be the presenting complaint in AIDS.⁴⁵⁹ *Bartonella* infection has not been detected in lesions of granuloma annulare.⁴⁶⁰ Interstitial granuloma annulare has been reported in borreliosis,⁴⁶¹ but it may represent a pattern related to the *Borrelia* infection.

It has been suggested that the underlying cause of the necrobiotic granulomas is an immunoglobulin-mediated vasculitis.⁴⁶² In a recent study, neutrophils and neutrophil fragments were commonly present in early lesions, but a true vasculitis was rare. Direct immunofluorescence studies did not demonstrate immune deposits in vessel walls.⁴⁶³ Other studies have stressed the importance of cell-mediated immune mechanisms with a delayed hypersensitivity reaction of T helper (Th) 1 type against as yet undefined antigens.^{464,465} This is supported by the finding of increased levels of interleukin (IL)-18, IFN- γ , and IL-2 in lesional skin.⁴⁶⁶ Collagen synthesis is increased in the lesions of granuloma annulare, probably representing a reparative phenomenon.⁴⁶⁷

The most widely used drugs are topical and systemic corticosteroids, but they are not always effective, and relapses may occur when they are discontinued.⁴⁶⁵ Other therapies have included cryosurgery, laser,⁴⁶⁸ retinoids,⁴⁶⁹ vitamin E and a 5-lipoxygenase inhibitor,⁴⁷⁰ dapsone, chloroquine, ultraviolet A1 phototherapy,^{465,471} narrowband ultraviolet B therapy,⁴⁷² combination therapy including calcineurin inhibitors,⁴⁷³ imiquimod cream,⁴⁷⁴ T-cell directed therapies such as infliximab, efalizumab, etanercept,^{466,475} and adalimumab,³⁴⁴ hydroxyurea,⁴⁷⁶ and various forms of laser therapy.^{477,478}

Histopathology

Three histological patterns may be seen in granuloma annulare – necrobiotic (collagenolytic) granulomas, an interstitial or 'incomplete' form, and granulomas of sarcoidal or tuberculoid type. The third of these patterns is uncommon.⁴⁷⁹ In most histopathological studies, the interstitial form is most common.⁴⁸⁰

In the form with *necrobiotic (collagenolytic) granulomas*, one or more areas of necrobiosis, surrounded by histiocytes and lymphocytes, are present in the superficial and mid dermis (Fig. 7.7). The peripheral rim of histiocytes may form a palisaded pattern (Fig. 7.8). Variable numbers of multinucleate giant cells are found in this zone. Some histiocytes have an epithelioid appearance. An increased mitotic rate is found in the histiocytes in some cases.⁴⁸¹ The histiocytes are CD68⁺.³³⁸ Surprisingly, in one series, the histiocytic component of the infiltrate stained only for vimentin and lysozyme and not the other common histiocyte markers (HAM56, CD68 (KP1), Mac-387, and factor XIIIa).⁴⁸² PGM1, the most specific histiocytic marker, is strongly expressed in all cases.^{483,484} A perivascular infiltrate of lymphocytes and histiocytes is also present; eosinophils are found in 40–66% of cases, but plasma cells are rare.^{485,486} Occasionally, there may be an accompanying superficial and deep, dense nodular lymphocytic infiltrate composed predominantly of T cells – features described in 'pseudolymphoma'.⁴⁸⁷ Granulomatous perineural inflammation is an uncommon finding.⁴⁸⁸ The central necrobiotic areas contain increased amounts of connective tissue mucins that may appear as basophilic

Figure 7.7 Granuloma annulare. The inflammatory cell infiltrate surrounds the area of 'necrobiosis' (collagenolysis) on all sides. It is not 'open ended' as in necrobiosis lipoidica. (H&E)

stringy material between collagen bundles. Neutrophils and nuclear dust contribute to the basophilic appearance. Special stains such as colloidal iron and Alcian blue aid in the demonstration of mucin. Heparan sulfate is present in addition to hyaluronic acid.^{489,490} Elastic fibers may be reduced, absent, or unchanged in the involved skin.^{491,492} The colocalization of granuloma annulare and mid-dermal elastolysis⁴⁹³ and granuloma annulare and elastolytic giant cell granuloma⁴⁹⁴ have also been reported.

Occasionally, neutrophils or nuclear fragments are present in necrobiotic areas.⁴⁶³ In the rare follicular-pustulous form, there are neutrophils in the upper portion of the follicles leading to pustule formation.³²⁷ Palisading necrobiotic granulomas surround hair follicles.⁴⁹⁵ An acute or subacute vasculitis has been described in or near foci of necrobiosis, associated with varying degrees of endothelial swelling, necrosis of vessel walls, fibrin exudation, and nuclear dust.⁴⁶²

The lesions of subcutaneous or *deep granuloma annulare* have areas of necrobiosis that are often larger than in the superficial type (Fig. 7.9). These foci are distributed in the deep dermis, subcutis, and, rarely, deep soft tissues.^{361,496} There may be overlying superficial dermal lesions. Eosinophils are said to be more common in this variant than in the superficial lesions.

In the *juxta-articular nodular form* of granuloma annulare (pseudorheumatoid nodules), there are deep dermal nodules with subcutaneous extension composed of epithelioid granulomas separated by thickened collagen bundles. Eosinophilic material, composed predominantly of collagen, is surrounded by histiocytes in a palisaded array. This differs from the usual form of granuloma annulare, in which this material is mucin. Scanty mucin is often present in this juxta-articular form. The interstitial form of granuloma annulare is present next to the nodules in approximately half of the cases, further supporting the notion that the nodular lesions are a form of granuloma annulare.³⁶²

In the *disseminated form* of granuloma annulare, the granulomatous foci are often situated in the papillary dermis (Fig. 7.10). Necrobiosis may be inconspicuous.

In the *interstitial or 'incomplete' form* of granuloma annulare, the histological changes are subtle and best assessed at lower power. The dermis has a 'busy' look due to increased numbers of inflammatory cells, mainly histiocytes and lymphocytes (Fig. 7.11). They are arranged about vessels and between collagen bundles that are separated by increased connective tissue mucin. There are no formed areas of necrobiosis. In some cases, the interstitial component is minimal.

Figure 7.8 Granuloma annulare. (A) A palisade of inflammatory cells surrounds the central zone of 'necrobiosis' (collagenolysis). (B) There is some nuclear dust within this central zone. (H&E)

Figure 7.9 Subcutaneous granuloma annulare. There are large areas of 'necrobiosis' surrounded by a palisade of lymphocytes and histiocytes. (H&E)

Figure 7.10 Disseminated granuloma annulare with involvement of the papillary dermis. There are no acanthotic downgrowths of rete pegs at the margins of the inflammatory focus, as seen in lichen nitidus. 'Necrobiosis' may be subtle in this form of granuloma annulare. (H&E)

Figure 7.11 (A) Granuloma annulare of 'incomplete' type. (B) The dermis is hypercellular (a so-called 'busy dermis'). (H&E) (C) There is an increased amount of interstitial mucin. (Alcian blue)

Figure 7.12 Sarcoidal granuloma annulare. A single field can closely resemble sarcoidosis, although the granuloma is not completely 'naked'. (H&E)

Figure 7.13 Perforating granuloma annulare. (H&E)

Cases of the non-necrobiotic *sarcoidal or tuberculoid type* of granuloma annulare are uncommon and pose a diagnostic problem. The presence of increased dermal mucin or eosinophils may be helpful distinguishing features (Fig. 7.12).

In most cases of granuloma annulare, the epidermal changes are minimal. *Perforating* lesions have a central epidermal perforation that communicates with an underlying necrobiotic granuloma (Fig. 7.13). At the edges of the perforation, there are varying degrees of downward epidermal hyperplasia to form a channel. The channel contains necrobiotic material and cellular debris.³⁴⁸ There is surface hyperkeratosis.³²⁴ The lesions sometimes perforate by way of a hair follicle.⁴⁹⁷ Pustules are a very rare finding in the perforating variant.³²⁷

Immunofluorescence studies have shown fibrin in areas of necrobiosis.⁴⁹⁸ IgM and C3 were present in blood vessel walls in one series.⁴⁶² Immunoperoxidase techniques have demonstrated activated T lymphocytes with an excess of helper/inducer phenotype (CD4⁺) and CD1⁺ dendritic cells related to Langerhans cells in the perivascular and granulomatous infiltrates.⁴⁶⁴ In contrast, lymphocytes were predominantly of CD8 type in a patient with HIV infection.⁴⁹⁹ A study of the staining pattern of lysozyme in the inflammatory cell infiltrate suggests that this may be useful in distinguishing granuloma annulare from other necrobiotic granulomas.⁵⁰⁰ The distribution of the inhibitor of metalloproteinase-1 is different in granuloma annulare and necrobiosis lipoidica.⁵⁰¹

Table 7.2 Necrobiotic (collagenolytic) granulomas (after Lynch and Barrett)	
'Blue' granulomas	'Red' granulomas
Granuloma annulare	Necrobiosis lipoidica
Wegener's granulomatosis	Necrobiotic xanthogranuloma
Rheumatoid vasculitis	Rheumatoid nodule
	Pseudorheumatoid nodules of adults
	Churg–Strauss syndrome
	Eosinophilic cellulitis (Wells' syndrome)

Note: Additional rare causes of necrobiotic granulomas include injected bovine collagen, *Trichophyton rubrum* infection, suture material, berylliosis, injection sites of drugs of abuse, hepatitis B vaccine, disodium clodronate, ataxia–telangiectasia, parvovirus B19 infection, and metastatic Crohn's disease.

Electron microscopy

Ultrastructural studies have confirmed the presence of histiocytes in the dermal infiltrate together with cellular debris and fibroblasts. Degenerative changes in collagen in areas of necrobiosis include swelling, loss of periodic banding, and fragmentation of fibers. Elastic fibers also show degenerative changes. Fibrin and other amorphous material is present in interstitial areas.⁵⁰²

Differential diagnosis

Granuloma annulare must be distinguished from other necrobiotic granulomas. *Necrobiosis lipoidica* typically shows horizontally oriented foci of amorphous, eosinophilic necrobiosis, with intervening zones of granulomatous inflammation often horizontally oriented and layered between areas of necrobiosis (the 'sandwich sign'). In granuloma annulare, the intervening areas of dermis between the necrobiotic granulomas are relatively normal compared with necrobiosis lipoidica, and there is no fibrosis. Plasma cells, which are inconspicuous in granuloma annulare, are readily identified and sometimes numerous in necrobiosis lipoidica. Granulomas tend to be better developed in necrobiosis lipoidica and often include multinucleated giant cells, whereas in contrast to granuloma annulare, mucin is not generally demonstrable in the necrobiotic areas. Based on these changes, Lynch and Barrett classified granuloma annulare as a 'blue' granuloma, in contrast to 'red' necrobiotic (collagenolytic) granulomas (of which necrobiosis is an example), in which fibrin, eosinophils, or flame figures contribute to an eosinophilic appearance.^{321,503} Although this is an oversimplification of a sometimes difficult assessment, the various 'blue' and 'red' granulomas are listed in Table 7.2. There is often a close resemblance between subcutaneous granuloma annulare and *rheumatoid nodule*. The mean age of patients with subcutaneous granuloma annulare (second decade) is significantly less than that for rheumatoid nodule (sixth decade), and patients with subcutaneous granuloma annulare usually do not have symptoms or signs of arthritis. Microscopically, rheumatoid nodules tend to have fibrinous eosinophilic necrobiosis, giant cells within palisaded foci, and significant stromal fibrosis, whereas subcutaneous granuloma annulare demonstrates edematous-appearing to mucinous necrobiosis, a lack of giant cells, and lesser degrees of fibrosis. Typically, mucin stains are positive in the necrobiotic foci of granuloma annulare and not in those of rheumatoid nodule, but there can be overlap of these findings. Therefore, one should not depend on the results of mucin stains alone in distinguishing between these two disorders. The eosinophilic material in juxta-articular, nodular granuloma annulare also contrasts with rheumatoid nodules in which the central material is fibrin. *Actinic granuloma (annular elastolytic giant cell granuloma)* shares with granuloma annulare the annular clinical appearance, the presence of granulomas in the dermis, and the phenomenon of elastolysis so that some authorities regard it as simply a variant of

granuloma annulare. However, the granulomas of actinic granuloma tend to be less organized than those in the palisaded type of granuloma annulare, and they feature more multinucleated giant cells, a lack of significant necrobiosis, and little or no mucin deposition. An elliptical biopsy taken across the active lesional border in actinic granuloma will show granulomas with ingestion of elastic fibers in the middle zone, fibrosis with an absence of elastic fibers in the dermis inside the expanding border, and normal-appearing dermis, with preserved solar elastosis, outside the expanding border. *Granuloma multiforme* (Mkar disease), a condition seen predominantly in central African countries, has clinical and histopathologic resemblances to both granuloma annulare and actinic granuloma, and it may in fact represent a variant of those disorders.

There is some superficial resemblance of lesions of disseminated granuloma annulare to lichen nitidus (see p. 49), although in disseminated granuloma annulare there are no acanthotic downgrowths of the epidermis at the periphery of the lesions.

With regard to interstitial granuloma annulare, a similar appearance can be seen in the interstitial granulomatous drug reaction (see p. 216), although in the latter condition true necrobiosis is uncommon and, if present, localized. Furthermore, eosinophils are often present, and there may be lichenoid changes at the dermal–epidermal interface. In interstitial granulomatous dermatitis, there are both neutrophils and eosinophils in the infiltrate, although both cell types may be sparse. Another characteristic feature is the presence of a palisade of histiocytes around one or many collagen fibers, which often have a basophilic hue. Rarely, *M. marinum* infection of the skin may mimic interstitial granuloma annulare.⁵⁰⁴ It is uncertain whether the cases of this type of granuloma annulare associated with borreliosis are mimics or true examples of granuloma annulare.⁴⁶¹ Other mimics include granulomatous mycosis fungoides and B-cell lymphoma.⁵⁰⁵ In fact, interstitial granuloma annulare and patch stage mycosis fungoides can also coexist.⁴³⁰ One study showed that T-cell receptor gene rearrangement analysis is helpful in differentiating granulomatous T-cell lymphomas from the benign granulomatous mimics, sarcoidosis and granuloma annulare; interestingly, however, a monoclonal T-cell population was found in 2 of 15 cases of granuloma annulare in this study.⁵⁰⁶ Negative staining for both hemosiderin and human herpesvirus 8 can be used to distinguish interstitial granuloma annulare from early Kaposi's sarcoma in which both are usually positive.⁵⁰⁷ A recent example of secondary syphilis microscopically resembled interstitial granuloma annulare; differences from granuloma annulare included a plasma cell component to the infiltrate and the finding of spirochetes with immunohistochemical staining.⁵⁰⁸ In another report, a case initially believed to be interstitial granuloma annulare proved to be papular mucinosis; the true diagnosis was supported by dense, diffuse dermal mucin deposition and the association with a monoclonal gammopathy.⁵⁰⁹

The sarcoidal variant of granuloma annulare would by its very nature be difficult to distinguish from true *sarcoidosis*, although mucin deposits, eosinophils, or subtle areas suggesting interstitial granuloma annulare may be identified. Eosinophils and obvious mucin are not seen in sarcoidosis.⁴⁸⁵ However, granuloma annulare and sarcoidosis have been reported in the same patient.⁴⁹⁸

NECROBIOSIS LIPOIDICA

Necrobiosis lipoidica was originally called 'necrobiosis lipoidica diabeticorum' but, although some cases are associated with diabetes mellitus,^{510,511} it is not peculiar to diabetes.⁵¹² In one series, only 11% of patients with necrobiosis lipoidica had diabetes mellitus at presentation, whereas a further 11% developed impaired glucose tolerance/diabetes in the succeeding 15 years.⁵¹³ The incidence in diabetics is low – approximately 3 cases per 1000.⁵¹⁰ It is even lower in childhood diabetes.⁵¹⁴

The legs, particularly the shins, are overwhelmingly the most common site of involvement, but lesions may also occur on the forearms, hands, and trunk. Unusual sites include the nipple, penis, scrotum, surgical scars, a tattoo site, periorbital area, face, scalp, and a lymphedematous arm.^{515–525} Three-fourths of cases are bilateral at presentation, and many more become bilateral later. Lesions may be single but are more often multiple. Diffuse disease is rare.⁵²⁶ Females are affected more than males at a ratio of 3:1. The average age of onset in one series was 34 years, but the condition may be seen in children.^{527–529} It has occurred in monozygotic twins, but not until adult life.⁵³⁰

The earliest lesions are red papules that enlarge radially to become patches or plaques with an atrophic, slightly depressed, shiny yellow-brown center and a well-defined raised red to purplish edge. Nodules are uncommon.⁵³¹ Some lesions resolve spontaneously, but many are persistent and chronic and may ulcerate;^{532–534} this occurred in 13% of cases in one series.⁵³⁵ Rarely, squamous cell carcinoma may arise in long-standing lesions.^{536–541} The simultaneous occurrence of necrobiosis lipoidica with granuloma annulare^{542,543} and with sarcoidosis has been reported.^{544,545} It has also been associated with autoimmune thyroid disease, scleroderma, rheumatoid arthritis, and jejunoileal bypass surgery.^{546,547} The case reported in association with light-chain-restricted plasma cellular infiltrates^{546,548} has been questioned by others as not representing necrobiosis lipoidica.⁵⁴⁹

The association of these lesions with diabetes has already been discussed, but the role of this metabolic disorder in the development of the cutaneous lesions is not understood. Diabetic vascular changes may be important: in some early lesions, a necrotizing vasculitis has been described.⁵⁵⁰ Lesions show increased blood flow, refuting the hypothesis that the disease is a manifestation of ischemic disease.⁵⁵¹ The finding in areas of sclerotic collagen of Glut-1, a protein responsible for glucose transport across epithelial and endothelial barrier tissue, raises the possibility that a disturbance in glucose transport by fibroblasts may contribute to the histological findings.⁵⁵² Adults and children with insulin-dependent diabetes mellitus and necrobiosis lipoidica are at high risk for diabetic nephropathy and retinopathy.⁵⁵³ The detection of spirochetal organisms in patients with this disease from central Europe, by focus-floating microscopy, points to involvement of *Borrelia burgdorferi* or other strains in the development of this disease.⁵⁵⁴

The treatment of necrobiosis lipoidica includes topical and intralesional steroids, antiplatelet drugs such as aspirin and ticlopidine, and drugs that decrease blood viscosity such as pentoxifylline.⁵⁵⁵ Other agents that have been used with varying degrees of success include thalidomide,⁵⁵⁵ topical PUVA therapy,⁵⁵⁶ UVA1 phototherapy,⁵⁵⁷ photodynamic therapy,⁵⁵⁸ methotrexate,⁵⁵⁹ topical granulocyte–macrophage colony-stimulating factor (GM-CSF),⁵⁶⁰ pioglitazone,⁵⁶¹ antimalarial agents,⁵⁶² TNF- α inhibitors,^{563–565} and topical calcineurin inhibitors.^{566–569} A recent case reported resolution of long-standing necrobiosis lipoidica diabeticorum following 'pancreas after kidney' transplantation.⁵⁷⁰

Histopathology

Dermoscopy may be of some value in the preliminary diagnosis of necrobiosis lipoidica. Changes include branching telangiectasias and hairpin-like vessels on a yellowish background.⁵⁷¹ The histopathological changes in necrobiosis lipoidica involve the full thickness of the dermis and often the subcutis (Fig. 7.14). Early lesions are not often biopsied. They are said to show a superficial and deep perivascular and interstitial mixed inflammatory cell infiltrate in the dermis. Similar changes are present in septa of adipose tissue. A necrotizing vasculitis with adjacent areas of necrobiosis and necrosis of adnexal structures has also been seen.⁵⁵⁰

In active chronic lesions, there is some variability between cases. The characteristic changes are seen at the edge of the lesions. These

Figure 7.14 Necrobiosis lipoidica. There is involvement of the full thickness of the dermis with extension into the subcutis. (H&E)

Figure 7.15 Necrobiosis lipoidica. There are several layers of 'necrobiosis' within the dermis. (H&E)

changes involve most of the dermis but particularly its lower two-thirds. Areas of necrobiosis may be extensive or slight: they are often more extensive and less well-defined than in granuloma annulare (**Fig. 7.15**). The intervening areas of the dermis are also abnormal. Histiocytes, including variable numbers of multinucleate Langhans or foreign body giant cells, outline the areas of necrobiosis. The necrobiosis tends to be irregular and less complete than in granuloma annulare. There is a variable amount of dermal fibrosis and a superficial and deep perivascular inflammatory reaction that, in contrast to the usual picture in granuloma annulare, includes plasma cells (**Fig. 7.16**). Occasional eosinophils may be present.⁴⁸⁵ In some cases, necrobiotic areas are less frequent and there are collections of epithelioid histiocytes and multinucleate cells, particularly about dermal vessels. The dermal changes extend into the underlying septa of the subcutis and into the periphery

Figure 7.16 (A) Necrobiosis lipoidica. (B) A perivascular inflammatory cell infiltrate is present in the dermis. There is 'necrobiosis' of the adjacent collagen. (H&E)

of fat lobules. Lymphoid cell aggregates, containing germinal centers, are present in the deep dermis or subcutis in approximately 10% of cases of necrobiosis lipoidica.⁵⁷²

In old atrophic lesions and in the center of plaques, there is little necrobiosis and much dermal fibrosis. The underlying subcutis is also

fibrotic. Elastic tissue stains demonstrate considerable loss of elastic tissue. Scattered histiocytes may be present.

The presence of lipid in necrobiotic areas (demonstrated by Sudan stains) has been used in the past to distinguish necrobiosis lipoidica from granuloma annulare, but subsequent studies have also shown lipid droplets in granuloma annulare.⁴⁹² Cholesterol clefts may be present, uncommonly, in areas of necrobiosis.^{515,573} Rarely, they are a conspicuous feature.^{531,574} Fibrin can also be demonstrated in necrobiotic areas.⁵¹¹ There may be small amounts of mucin in the affected dermis, but the presence of large amounts in areas of necrobiosis favors a diagnosis of granuloma annulare.

Vascular changes are more prominent in necrobiosis lipoidica, particularly in the deeper vessels.³²² These range from endothelial swelling to a lymphocytic vasculitis and perivasculitis. Epithelioid granulomas may be present in the vessel wall or adjacent to it. In old lesions, the wall may show fibrous thickening. The smaller, more superficial vessels are increased in number and telangiectatic. Apart from atrophy and ulceration, epidermal changes are unremarkable in necrobiosis lipoidica. Transepidermal elimination of degenerate collagen has been reported;^{574,575} it may be associated with focal acanthosis or pseudoepitheliomatous hyperplasia. Transfollicular elimination also occurs.⁵⁷⁶

Immunofluorescence studies have demonstrated IgM and C3 in the walls of blood vessels in the involved skin. Fibrin is seen in necrobiotic areas. IgM, C3, and fibrinogen may be present at the dermoepidermal junction.⁵⁷⁷

Ultrastructural studies have shown degeneration of collagen and elastin in the lesions.⁵⁷⁸ Another study showed a decreased number of S100-positive nerves in plaques, in conformity with the cutaneous anesthesia that may be a feature of these lesions.⁵⁷⁹

Differential diagnosis

Fully developed lesions of necrobiosis lipoidica in pretibial locations generally show characteristic features and create minimal diagnostic difficulty. However, lesions in locations other than the lower legs may be more problematic. Although in most cases it is possible to distinguish necrobiosis lipoidica from *granuloma annulare*, there are cases in which this is difficult both clinically and histologically.⁵¹¹ By dermoscopy, granuloma annulare has a variable appearance, including dotted vessels, a red or white background, and pigmented structures – features that are not observed in necrobiosis lipoidica.⁵⁸⁰ Microscopically, the latter tends to show mucinous (blue-gray to blue) necrobiosis rather than the intensely pink-red, fibrinous necrobiosis of necrobiosis lipoidica; this mucin is sometimes apparent on routine staining but occasionally requires special stains such as colloidal iron or Alcian blue. The granulomas of granuloma annulare are more apt to consist of smaller macrophages and epithelioid cells with few multinucleated giant cells, and plasma cells are less conspicuous. However, there are occasional cases in which a distinction between these two disorders is almost impossible; in such cases, it may be that only a diagnosis of ‘necrobiotic granuloma’ can be rendered. Discrete, noncaseating granulomas in necrobiosis lipoidica can resemble those in *sarcoidosis*, but the associated eosinophilic necrobiosis would not be expected in the latter condition. However, coexistence of sarcoidosis, necrobiosis lipoidica, and/or granuloma annulare has been reported on multiple occasions, and in the literature there have been allusions to both morphologic and mechanistic relationships among all three of these granulomatous disorders. There may also be difficulties distinguishing between necrobiosis lipoidica and *necrobiotic xanthogranuloma* (see later). Cholesterol clefts and transepidermal elimination may occur in both these conditions. Clinical features are usually distinctive in necrobiotic xanthogranuloma, but not all cases are associated with paraproteinemia or a periorbital distribution of lesions.^{573,581} Lipid deposition is often obvious in necrobiotic xanthogranuloma even on routine staining, and it can be seen in the form of foamy macrophages

and Touton giant cells in addition to cholesterol cleft formation. Ordinarily, the lipid deposits of necrobiosis lipoidica are inconspicuous and can only be appreciated with special stains that do not work on formalin-fixed, paraffin-embedded tissues. In addition, granulomatous involvement of muscular vessels can be seen in necrobiotic xanthogranuloma but, to our knowledge, is not described in necrobiosis lipoidica. *Interstitial granulomatous dermatitis* differs from necrobiosis lipoidica in that it lacks broad zones of eosinophilic necrobiosis and tends to show collagen bundles with a basophilic, degenerative quality. Macrophages often surround isolated, degenerated collagen bundles; these are seen best in cross-section. The variety of interstitial granulomatous dermatitis associated with systemic disease usually has a neutrophilic component, whereas drug-induced lesions may show eosinophils and vacuolar alteration of the epidermal basilar layer. None of those features is typically seen in necrobiosis lipoidica. The septal panniculitis of necrobiosis lipoidica may resemble erythema nodosum, but in that condition there are no significant dermal changes. A recently described condition, pretibial angioplasia, has the clinical features of necrobiosis lipoidica but the microscopic characteristics of venous insufficiency.⁵⁸²

NECROBIOTIC XANTHOGRANULOMA

Necrobiotic xanthogranuloma is a rare condition characterized by the presence of violaceous to red, partly xanthomatous plaques and nodules; there is a predilection for the periorbital area. A paraproteinemia is often present. The clinical course is chronic. It is discussed further in Chapter 40, page 1156.

Histopathology

There are broad zones of hyaline necrobiosis as well as granulomatous foci composed of histiocytes, foam cells, and multinucleate cells (Fig. 7.17). The amount of xanthomatization is variable. Distinction from necrobiosis lipoidica is sometimes difficult on a small biopsy, but the clinical features of these two conditions are quite different.

RHEUMATOID NODULES

Skin manifestations, including rheumatoid nodules, are relatively common in rheumatoid arthritis.^{583,584} These nodules occur in

Figure 7.17 Necrobiotic xanthogranuloma. The ‘necrobiosis’ is only focal. Numerous giant cells are present. (H&E)

approximately 20% of patients, usually in the vicinity of joints. Sited primarily in the subcutaneous tissue, they may involve the deep and even the superficial dermis. They vary from millimeters to centimeters in size and consist of fibrous white masses in which there are creamy yellow irregular areas of necrobiosis. Old lesions may have clefts and cystic spaces in these regions. It is most probable that rheumatoid nodules result from a vasculitic process; however, even in very early lesions such a change may be difficult to demonstrate.⁵⁸⁵ Nodules usually persist for months to years. Rarely, similar lesions occur in systemic lupus erythematosus.⁵⁸⁶⁻⁵⁸⁸

Multiple small nodules may develop on the hands, feet, and ears during methotrexate therapy.⁵⁸⁹ This event is known as 'accelerated rheumatoid nodulosis'. The term rheumatoid nodulosis has also been used for the presence of subcutaneous rheumatoid nodules with recurrent articular symptoms but no significant synovitis. The rheumatoid factor is often negative.^{590,591} The distinction of this entity from juxta-articular pseudorheumatoid nodules is problematic.⁵⁹¹

Histopathology

There are one or more irregular areas of necrobiosis in the subcutis and dermis (Fig. 7.18). These areas are surrounded by a well-developed palisade of elongated histiocytes, with occasional lymphocytes, neutrophils, mast cells, and foreign body giant cells.⁵⁹² The central

Figure 7.18 (A) Rheumatoid nodule. (B) A palisade of elongated histiocytes surrounds a zone of 'necrobiosis'. (H&E)

necrobiotic focus is usually homogeneous and eosinophilic.⁵⁹³ There is sometimes obvious fibrin. In contrast, the areas of necrobiosis in the subcutaneous or deep variant of granuloma annulare are often pale and mucinous with a tendency to basophilia. Old rheumatoid nodules may show areas of dense fibrosis, clefts, and 'cystic' degeneration of the necrobiotic foci. The dermis and subcutis surrounding the necrobiotic granulomas show a perivascular round cell infiltrate that includes plasma cells. Eosinophils may be present. Uncommonly, an acute vasculitis is seen in the surrounding vessels, and sometimes a necrotic blood vessel associated with nuclear fragments or sparse neutrophils may be seen in the center of areas of necrobiosis. Occasionally, a superficial nodule may perforate the epidermis.⁵⁹⁴

Fibrin is present in the center of the necrobiotic areas.⁵⁹⁵ Rarely, immunoglobulins and complement have been demonstrated in vessels exhibiting a vasculitis. It is unusual to find mucin in necrobiotic foci in rheumatoid nodules, and this is the single most useful feature in distinguishing these lesions from the deep variant of granuloma annulare.⁵⁹³ In some cases of deep granuloma annulare, the changes are very similar to those of rheumatoid nodules; clinical information is most helpful in these instances.

RHEUMATIC FEVER NODULES

With the decline in the prevalence of rheumatic fever in developed countries, rheumatic nodules are now rarely seen or biopsied. Consequently, most histological studies are found in the older literature.⁵⁹⁶ Nodules are more common in children than adults and are usually associated with acute rheumatic carditis. They are usually asymptomatic and are distributed symmetrically over bony prominences, particularly at the elbows.⁵⁹⁷ Their size ranges from a few millimeters to 2 or 3 cm in diameter. The lesions, unlike rheumatoid nodules, last for only a short time and eventually involute.⁵⁹⁶

Histopathology

Rheumatic nodules form in the subcutis or in the tissue deep to it. They include one or more foci of altered collagen (fibrinoid necrosis or fibrinoid change): this change is characterized by separation and swelling of the collagen bundles and increased eosinophilia. These foci may contain scattered inflammatory cells⁵⁹⁷ or cell debris⁵⁹⁶ and are surrounded by histiocytes, sometimes arranged in palisaded array.⁵⁹⁶ Multinucleate histiocytes may be seen. A mixed inflammatory cell infiltrate is present at the periphery of these areas and around the vessels. Lipid may be seen in histiocytes about the altered collagen.⁵⁹⁶ Apparent differences in the published histological description of these lesions may reflect differences in their age, with early lesions being more exudative. A study of 40 rheumatic fever nodules, including ultrastructural features of two cases, has been published from India.⁵⁹⁸

REACTIONS TO FOREIGN MATERIALS AND VACCINES

Purified bovine collagen is currently being used, in the form of intracutaneous injections, to treat certain forms of superficial scarring (see p. 453). In some people, this results in a granulomatous reaction resembling granuloma annulare. There are irregular foci of eosinophilic necrobiosis surrounded by a palisading rim of multinucleate and mononuclear histiocytes, with lymphocytes and plasma cells.⁵⁹⁹

Areas of necrobiosis associated with a granulomatous reaction have also been described, rarely, in association with *Trichophyton rubrum* and with the presence of splinters of wood and suture material (Fig. 7.19).⁶⁰⁰⁻⁶⁰² Necrobiotic areas are also seen in cutaneous berylliosis.

Figure 7.19 Suture granuloma. There is a palisaded, centrally 'necrobiotic' granuloma to foreign material. (H&E)

Changes that superficially resemble necrobiotic granulomas are also seen in injection sites of drugs of abuse.⁶⁰³

Necrobiotic palisaded granulomas have been reported at the sites of injection of hepatitis B vaccine and of disodium clodronate.^{604,605}

MISCELLANEOUS DISEASES

Children with ataxia–telangiectasia may present with erythematous plaques that on histopathological examination show necrobiotic granulomas. As with other immunodeficiency diseases, granulomas of other types are often present. Tuberculoid and sarcoid granulomas have also been reported in ataxia–telangiectasia.⁶⁰⁶

Necrobiotic granulomas have also been reported in parvovirus B19 infection.⁴¹⁷ There is some resemblance to the lesions of granuloma annulare. Other times, the pattern is more like interstitial granulomatous dermatitis.

The extravascular granulomas of Churg–Strauss (allergic) granulomatosis and of Wegener's granulomatosis may have necrobiotic features. They are mentioned here for completeness, but they are considered further in Chapter 8, pages 271–274. Necrobiotic granulomas are a rare manifestation of systemic lymphoma.²⁰

Finally, Crohn's disease of so-called metastatic type may have necrobiotic granulomas.⁶⁰⁷

SUPPURATIVE GRANULOMAS

The suppurative granulomas consist of collections of epithelioid histiocytes, with or without multinucleate giant cells, in the centers of which are collections of neutrophils (Fig. 7.20). Most of the conditions included in this group are discussed in other chapters, and only the major differential histological features are noted here.

Suppurative granulomas are seen in the following conditions:

- Chromomycosis and phaeohyphomycosis
- Sporotrichosis
- Nontuberculous mycobacterial infections
- Blastomycosis
- Paracoccidioidomycosis
- Coccidioidomycosis
- Blastomycosis-like pyoderma
- Mycetoma, nocardiosis, and actinomycosis

Figure 7.20 Sporotrichosis. A suppurative granuloma is present. (H&E)

- Cat-scratch disease
- Lymphogranuloma venereum
- Pyoderma gangrenosum
- Ruptured cysts and follicles.

Histopathology

The first seven conditions listed previously show very similar histological changes, including marked irregular epidermal hyperplasia ('pseudoepitheliomatous' hyperplasia), intraepidermal and dermal microabscesses, suppurative granulomas, and a mixed inflammatory cell infiltrate that includes scattered multinucleate giant cells. Specific diagnosis depends on identification of the causative agent in tissue sections or by culture. Similar changes are seen in halogenodermas, but granulomas and giant cells are not seen, except in relation to ruptured hair follicles. It is necessary to cut multiple sections and carefully examine them for microorganisms when such a histopathological pattern is seen. Most organisms can be seen in routine histological sections if care is taken, but stains for fungi (e.g., the PAS and Grocott methenamine silver methods) and mycobacteria may reveal organisms that escape detection in hematoxylin and eosin preparations.

CHROMOMYCOSIS AND PHAEOHYPHOMYCOSIS

In chromomycosis, the characteristic organisms are round to oval thick-walled brown cells approximately 6–12 μm in diameter (sclerotic bodies and Medlar bodies). Intracellular septation may be seen. Single organisms or small groups are found within multinucleate giant cells, within microabscesses, suppurative granulomas, or surface crust. Tuberculoid granulomas are occasionally seen in the dermal infiltrate.⁶⁰⁸ In phaeohyphomycosis, which is clinically distinct from chromomycosis, there are hyphal and yeast forms in suppurative granulomas. Species identification requires culture of the organism. Chromomycosis and phaeohyphomycosis are discussed further in Chapter 25, pages 703–705.

SPOROTRICHOSIS

The causative organism, *Sporothrix schenckii*, is present in the lesions of primary cutaneous sporotrichosis (see p. 598) in the yeast form; it is only rarely found in its hyphal form. The formation of sporothrix

asteroids by the encasement of individual yeast cells by a deposit of immune complexes and fibrin is an occasional finding. These asteroids are seen infrequently in sporotrichotic lesions in some parts of the world, but are comparatively common in those seen in Australia and South Africa.⁶⁰⁹ The yeast cells are small, round to oval structures, some of which show budding. They may be found within giant cells or in suppurative granulomas. They are difficult to see and may require PAS stains for recognition. The asteroids are found only in microabscesses and the centers of suppurative granulomas. They can be recognized in these locations on careful study of hematoxylin and eosin preparations. Generally, organisms are few in sporotrichosis.

NONTUBERCULOUS MYCOBACTERIAL INFECTIONS

Tuberculoid or suppurative granulomas may be seen in infections caused by nontuberculous mycobacteria, including *M. marinum* and *M. chelonae* (see p. 654). In *M. marinum* infections, caseation is not usually seen. Organisms are sparse; when found, they are usually within histiocytes. Organisms may be moderately plentiful in *M. chelonae* infections. They are frequently seen in and about round to oval clear spaces in the center of suppurative foci.

Rarely, these infections may present with a lichenoid as well as a granulomatous dermatitis.⁶¹⁰

BLASTOMYCOSIS

In the disseminated form of blastomycosis, the organisms are scarce and are found either within giant cells or free in the dermis (see p. 698). The organism (*Blastomyces dermatitidis*) is a thick-walled round cell, 8–15 µm in diameter. Multiple nuclei may be seen in the cell. Single broad-based buds are occasionally present on the surface. PAS or Grocott methenamine silver stains facilitate demonstration of the organism.

PARACOccIDIOIDOMYCOSIS

Most cutaneous lesions in paracoccidioidomycosis ('South American blastomycosis') are secondary lesions seen in the course of the disseminated form of the disease (see p. 700). The causative agent, *Paracoccidioides brasiliensis*, is usually found in giant cells. The organisms vary more in size than *B. dermatitidis* and can be larger. Also, *P. brasiliensis* is thin walled, lacks multiple nuclei, and often has multiple buds arranged round the mother cell.

COCCIDIOIDOMYCOSIS

The cutaneous lesions of coccidioidomycosis are almost always secondary to pulmonary disease (see p. 699). Areas of necrosis are sometimes present in the dermis. Sporangia of *Coccidioides immitis* are rounded structures, 10–80 µm in diameter, which contain multiple sporangiospores that are 1–5 µm in diameter. Sporangia are usually easily identified in sections stained with hematoxylin and eosin. Spherules and sporangiospores stain with silver stains. Sporangiospores are PAS positive, whereas spherules may be negative or only weakly positive.⁶¹¹

BLASTOMYCOSIS-LIKE PYODERMA

Marked epidermal hyperplasia and epidermal, follicular, and dermal abscesses are seen in blastomycosis-like pyoderma (see p. 646). There is usually severe solar elastosis. In some cases, a palisading rim of histiocytes is seen surrounding the suppurative foci in the dermis.

Multinucleate giant cells are occasionally present in this zone, but they are not as common as in the mycoses discussed previously. Bacteria, particularly gram-positive cocci, may be seen in suppurative foci. *Staphylococcus aureus* is often isolated from tissue samples but not from the skin surface.

MYCETOMAS, NOCARDIOSIS, AND ACTINOMYCOSIS

In mycetomas, nocardiosis, and actinomycosis, foci of suppuration may become surrounded by a histiocytic rim to form suppurative granulomas. Organisms are present within the suppurative foci. These conditions are discussed in Chapter 25, pages 707–710.

CAT-SCRATCH DISEASE

Suppurative granulomas and zones of necrosis surrounded by a palisade of epithelioid cells may be seen in the skin, at the site of injury, in cat-scratch disease (see p. 668). A variable number of lymphocytes, plasma cells, histiocytes, and eosinophils are present in the adjacent tissues.⁶¹²

LYMPHOGRANULOMA VENEREUM

The cutaneous lesions of lymphogranuloma venereum do not have a specific histopathological appearance (see p. 670). The characteristic suppurative and centrally necrotic granulomas are found in the regional lymph nodes.⁶¹²

PYODERMA GANGRENOsum

Superficial granulomatous pyoderma is a variant of pyoderma gangrenosum (see p. 269) that has a more indolent course than classic pyoderma gangrenosum.^{613,614} One group has suggested that this condition would be better called 'pathergic granulomatous cutaneous ulceration'.⁶¹⁵ Unlike the typical pyoderma gangrenosum, there are suppurative granulomas and scattered multinucleate giant cells in the dermis associated with irregular epidermal hyperplasia, sinus formation, fibrosis, and a heavy mixed inflammatory infiltrate that includes plasma cells and eosinophils.^{614,616} The histological changes mimic an infectious process, but the lesions respond to corticosteroid therapy and not antibiotics.

RUPTURED CYSTS AND FOLLICLES

Occasionally, suppurative granulomas are seen adjacent to ruptured cysts (epidermal and dermoid cysts, in particular) and to inflamed hair follicles that rupture, liberating their contents into the dermis.

FOREIGN BODY GRANULOMAS

The essential feature of foreign body granulomas is the presence either of identifiable *exogenous* (foreign) material or of *endogenous* material that has become altered in some way so that it acts as a foreign body. Around this material are arranged histiocytes (including epithelioid histiocytes), multinucleate giant cells derived from histiocytes, and variable numbers of other inflammatory cells. Multinucleate giant cells are often of foreign body type, with nuclei scattered irregularly throughout the cytoplasm, but Langhans giant cells are also seen. In some cases, the reaction consists almost entirely of multinucleate cells.

Figure 7.21 Foreign body granuloma. There is tattoo pigment present. (H&E)

Where there are moderate to large amounts of foreign material, histiocytes are sometimes arranged in an irregular palisade. Some foreign materials, such as tattoo pigment, induce granulomas of different types. The causative agent may or may not be birefringent when sections are examined in polarized light.

EXOGENOUS MATERIAL

Foreign body granulomas are formed around such disparate substances as starch,⁶¹⁷ talc,⁶¹⁸ tattoo material (Fig. 7.21),^{206,619} cactus bristles,⁶²⁰ wood splinters, suture material, retained gauze fibers ('gauzoma') many years after an orthopedic surgical procedure,⁶²¹ retained epicardial pacing wires,^{622,623} Bioplastique®, Dermalive® and Artecoll® microimplants,^{624–627} injected mineral oil,⁶²⁸ injected hyaluronic acid,^{629–632} hyaluronic acid/dextranomer microsphere filler injection,⁶³³ pencil lead,⁶³⁴ bovine collagen,⁶³⁵ artificial hair,⁶³⁶ golf club graphite,⁶³⁷ fragments of a chain saw blade,⁶³⁸ and insect mouthparts.⁶³⁹ Some foreign materials, such as glass, zirconium,⁶⁴⁰ beryllium, acrylic fibers, and tattoo pigments, may induce local sarcoid-like granulomas (see p. 194). Tuberculoid granulomas have been reported in one patient at the site of injection of zinc-containing insulin.⁶⁴¹ Granulomatous reactions have appeared suddenly to long-implanted material as a feature of the immune reconstitution syndrome associated with the use of HAART for HIV infection.⁶⁴² Multiple linear nodules, composed of granulomas of foreign body type, have developed along the superficial veins on both arms in an HIV-positive intravenous drug user treated with HAART.⁶⁴³

Talc particles are birefringent, as are starch granules; the latter exhibit a characteristic Maltese cross birefringence in polarized light.⁶⁴⁴ Incidentally, it is not well-known that cryptococci may also be birefringent in polarized light. Materials used to 'cut' heroin and other addictive drugs and the filler materials in crushed tablets may produce cutaneous foreign body granulomas in intravenous drug abusers.⁶⁴⁵ The elemental nature of unknown inorganic material can be determined using energy-dispersive X-ray analysis techniques if necessary. A granulomatous reaction has been recorded at the base of the penis following the injection of acyclovir (aciclovir) tablets dissolved in hydrogen peroxide in the self-treatment of recurrent genital herpes infection.⁶⁴⁶

Plant material may be readily identified by its characteristic structure and may be PAS positive.⁶²⁰ It is prudent to perform stains for bacteria and fungi to exclude contaminating organisms when foreign bodies such as wood splinters or bone fragments are found. **Pulse**

Figure 7.22 Pulse granuloma. There is foreign material present and hyaline thickening of adjacent vessel walls, so-called 'hyalin angiopathy'. (H&E)

granulomas (Fig. 7.22) are rare reactions to particles of food that are characterized by clusters of small to medium-sized hyaline rings.^{647,648} They may be seen around fistulae involving the gastrointestinal tract; oral and perianal pulse granulomas have also been reported.^{649,650} Because the hyaline material usually involves vessel walls, cases have also been reported as (giant cell) hyalin angiopathy (see p. 444).

A granulomatous reaction at the site of an arthropod bite may be a reaction to insect fragments or introduced epidermal elements.⁶³⁹ A florid granulomatous reaction producing an exophytic tumor has been reported following multiple bee stings used as a folk remedy.⁶⁵¹

A granulomatous reaction is sometimes seen about certain types of suture material, including nylon, silk, and Dacron®.⁶⁵² Each type of suture material has a characteristic appearance and birefringence pattern in tissue sections.

Immunization with aluminum-adsorbed vaccines such as tetanus toxoid may produce an unusual foreign body reaction.^{653,654} A central zone of granular debris containing aluminum and phosphate is surrounded by a rim of granular histiocytes (see p. 450). A marked lymphoid infiltrate with lymphoid follicles and eosinophils is present at the periphery. This may superficially resemble the changes of Kimura's disease. The granulomatous reaction involving a Mantoux test site may have resulted from the implantation of epidermal keratin during the intradermal injection.⁶⁵⁵ The foreign body granuloma that resulted from a BCG vaccination was probably due to the presence of monosodium glutamate in the vaccine.⁶⁵⁶ Granulomatous inflammation of the penis has followed intravesical treatments with BCG. The nature of the reactions was never completely elucidated, but it was thought to be a BCG-related granulomatous reaction.⁶⁵⁷ A granulomatous reaction of mixed foreign body and sarcoid-like types has followed the use of depot formulations of leuporelin acetate in the treatment of prostate cancer.⁶⁵⁸

A granulomatous reaction has been reported on the eyelids following the use of aluminum salts in blepharopigmentation, a process that attempts to produce a permanent line along the eyelid margin, simulating a cosmetic eyeliner.^{659,660} A similar cosmetic tattoo has been reported on the lips.⁶⁶¹ Titanium alloys used in ear piercing are a rare cause of a granulomatous reaction.⁶⁶²

Granulomas have been described in the skin at the point of entry of acupuncture, indwelling catheter, and venepuncture needles coated with silicone.^{663–665} Particles of silicon were detected in macrophages by X-ray microanalysis. Silica granulomas of the elbow have been

reported in a tennis player as a consequence of falls on a tennis court that was covered with an artificial silica/polypropylon grass surface.⁶⁶⁶ Silicone granulomas have followed its injection into various sites for cosmetic purposes.⁶⁶⁷⁻⁶⁶⁹ Their origin was not determined in another case.⁶⁷⁰ They are discussed further in Chapter 14, page 453.

ENDOGENOUS MATERIAL

Endogenous materials include calcium deposits, urates, oxalate,^{671,672} keratin, and hair.

Both metastatic and dystrophic calcification may be associated with a granulomatous foreign body reaction. This is also seen in idiopathic calcinosis of the scrotum and subepidermal calcified nodules.

A granulomatous reaction to keratin and hair shafts occurs adjacent to ruptured epidermal, pilar, and dermoid cysts, pilomatrixomas, and any condition associated with rupture or destruction of a hair follicle. Granulomas have been reported as a reaction to autologous hairs incarcerated during hair transplantation.⁶⁷³ A similar reaction is seen in the interdigital web spaces of barbers from implanted hair.^{674,675} It is not uncommon for enlargement of a banal nevocellular nevus to be due to a granulomatous reaction following damage to a hair follicle. Fragments of keratin may or may not be found in these reactions. Occasional fine wavy eosinophilic squames may be identifiable within spaces in the dermis or within giant cells. Hair shafts are oval or rounded structures when cut in section and sometimes exhibit cortical and medullary layers: they are variably birefringent in polarized light and acid fast when stained by the Ziehl-Neelsen technique. Foreign body granulomas to keratin are also seen near squamous cell carcinomas and in recurrences. Their presence is an indication for a careful search for residual tumor.⁶⁷⁶

Cutaneous amyloid is usually inert, but in nodular amyloidosis it may occasionally provoke a foreign body giant cell reaction.

XANTHOGRANULOMAS

Xanthogranulomas are granulomas composed of numerous histiocytes with foamy/pale cytoplasm and a variable admixture of other inflammatory cells and some Touton giant cells. The diseases in this category are considered in Chapter 40, pages 1149–1157.

The prototype disease for this category is juvenile xanthogranuloma, but the other non-Langerhans cell histiocytoses are also included.¹ In addition, the xanthomas can be considered in this category, although there are usually only sparse or no inflammatory cells in some of these diseases. Reticulohistiocytoma is another example.¹

MISCELLANEOUS GRANULOMAS

The miscellaneous category includes conditions that do not fit neatly into any of the more established categories of granulomatous disease.

The following conditions are discussed in this section:

- Chalazion
- Melkersson–Rosenthal syndrome
- Elastolytic granulomas
- Annular granulomatous lesions in ochronosis
- Granulomas in immunodeficiency disorders
- Interstitial granulomatous dermatitis
- Interstitial granulomatous drug reaction
- Superantigen id reaction
- Granulomatous T-cell lymphomas.

Figure 7.23 Chalazion. A clear space represents lipids that have been removed during processing. Surrounding the clear space are a few neutrophils, along with epithelioid macrophages, lymphocytes, and plasma cells.

CHALAZION

A chalazion is a solitary, usually painless lesion of the eyelid that results from a granulomatous reaction to lipid released from a blocked sebaceous gland. It is best visualized when the lid is everted. Recurrent lesions may occur in patients with seborrheic dermatitis and rosacea.

Histopathology

The granulomatous reaction in a chalazion has mixed tuberculoid and foreign body features. Sometimes there is associated suppuration as well, with small collections of neutrophils. In the center of the granuloma, there is a characteristic clear space resulting from lipids that have been removed during processing. There is a heavy chronic inflammatory cell infiltrate surrounding the granuloma(s). The infiltrate is composed of lymphocytes, some plasma cells, and a few neutrophils (Fig. 7.23).

MELKERSSON–ROSENTHAL SYNDROME⁶⁷⁷

The Melkersson–Rosenthal syndrome is a rare condition of unknown etiology characterized by the triad of chronic orofacial swelling predominantly involving the lips, recurrent facial nerve palsy, and a fissured tongue (lingua plicata).⁶⁷⁸⁻⁶⁸³ The complete triad occurs in approximately 25% of cases. A monosymptomatic form in which there is localized episodic swelling of the lip(s) has been called cheilitis granulomatosa of Miescher or granulomatous cheilitis.⁶⁸⁴⁻⁶⁸⁷ The term ‘**orofacial granulomatosis**’ was introduced by Wiesenfeld and colleagues in 1985 to cover both granulomatous cheilitis and Melkersson–Rosenthal syndrome.⁶⁷⁸ Anogenital granulomatosis has been regarded as the counterpart of orofacial granulomatosis.^{688,689} Crohn’s disease and sarcoidosis need exclusion. Some of these cases were called vulvitis granulomatosa in the past.^{688,690} The concomitance of granulomatous cheilitis and vulvitis is extremely rare.^{691,692}

The presenting complaint is usually swelling of the lips, but adjacent areas of the cheek are frequently involved.⁶⁸³ The initial facial swelling may last only a few days and be soft and fluctuant, but it becomes firmer and persistent with time.⁶⁹³ Facial nerve palsy, usually unilateral,

occurs in 13–50% of cases.^{678,694} Facial swelling has also been reported in association with syringomyelia.⁶⁹⁵ The median age at onset was 20 years in one series, and there was an equal sex incidence.⁶⁷⁸ Persistent unilateral orbital and eyelid edema is an extremely rare manifestation of the disease.^{696,697} Multiple cranial nerve palsies were reported in one case.⁶⁹⁸

The etiology is unknown, but the syndrome has been considered to be a manifestation of sarcoidosis,⁶⁹⁹ a reaction to infection or to foreign material, such as silicates, gold, and mercury,⁷⁰⁰ and a delayed hypersensitivity to cow's milk protein or food additives.⁷⁰¹ In one case, it was worsened by the cocoa in drinking chocolate.⁷⁰² *Borrelia burgdorferi* has been excluded as an etiological agent,⁷⁰³ but the DNA of *M. tuberculosis* has been identified by PCR in one case.⁷⁰⁴ In a further case, the granulomatous cheilitis was regarded as the consequence of a tuberculid.⁷⁰⁵ Elimination of odontogenic infections has produced remission in some cases.⁷⁰⁶

Occasional cases have been associated with other granulomatous skin lesions or granulomatous lymphadenopathy.^{678,707} A granulomatous cheilitis may be a manifestation of Crohn's disease.^{318,708–710} The lip sign may predate gastrointestinal symptoms by years.^{711,712} There is one report of a patient with Crohn's disease and the full triad of lesions associated with the Melkersson–Rosenthal syndrome.⁷¹³ In a retrospective study from Israel, there was a 50% prevalence of psoriasis among 12 patients with Melkersson–Rosenthal syndrome.⁷¹⁴

Granulomatous cheilitis has been successfully treated with clofazimine, thalidomide, and infliximab.^{709,715,716} Triamcinolone injections have also been used, both alone^{717,718} and combined with dapsone.^{719,720} Sometimes surgical treatment is necessary for the persistent macrocheilia that may occur with Melkersson–Rosenthal syndrome and cheilitis granulomatosa.^{721,722} Amalgam removal resulted in the resolution of another case.⁷²³

Histopathology

There is marked edema in the dermis together with a perivascular inflammatory cell infiltrate consisting of lymphocytes, plasma cells, histiocytes, and occasional eosinophils; the infiltrate may extend into underlying muscle. Small 'naked' collections of epithelioid cells, loose tuberculoid granulomas with a peripheral round cell infiltrate, or isolated multinucleate giant cells are usually present. Intralymphatic granulomas were demonstrated in one case and postulated to be a cause of tissue edema.⁷²⁴ The inflammatory infiltrate is more consistently related to vessels than that in sarcoidosis (Fig. 7.24). Schaumann bodies and birefringent fragments may occasionally be seen in histiocytes and giant cells. Lymphatics are usually widely dilated and may contain collections of inflammatory cells. Alternatively, inflammatory cell collections may bulge into the lumen of vessels.⁷²⁵ Older lesions may show dermal fibrosis. Collagenous nodules that represent fibrosed granulomas may be found after treatment with steroids.⁷²⁶ Overlying epithelial changes are nonspecific. There are no reliable features to allow distinction of those cases that represent a manifestation of Crohn's disease.

Similar histological changes are seen in association with chronic edema and swelling of the vulva and penis in some cases of recurrent infections of this region.^{689,727} Squamous cell carcinoma of the vulva has been reported in long-standing vulvitis granulomatosa.⁷²⁸

The violaceous lesions reported in patients with rheumatoid arthritis as **cutaneous histiocytic lymphangitis** and **angioendotheliomatosis** have some histological similarities to both Melkersson–Rosenthal syndrome and angioendotheliomatosis.^{729,730} Both reports appear to be describing the same entity. There were dilated lymphatics in the dermis containing aggregates of inflammatory cells, mainly histiocytes, with adjacent lymphoid aggregates, but no granulomas as seen in Melkersson–Rosenthal syndrome. Granulomas were present in another case with intralymphatic histiocytosis associated with orthopedic

Figure 7.24 (A) Melkersson–Rosenthal syndrome. (B) A granulomatous reaction is present adjacent to a vessel containing inflammatory cells. (H&E)

metal implants.⁷³¹ The term **intravascular histiocytosis** is now the preferred title for this entity (see p. 1161).

ELASTOLYTIC GRANULOMAS

The elastolytic granulomas predominantly affect the exposed skin of the head, neck, and limbs. This group of granulomatous conditions includes actinic granuloma,⁷³² annular elastolytic giant cell granuloma, atypical necrobiosis lipoidica of the face and scalp,⁷³³ and Miescher's granuloma.⁷³⁴ They are all characterized by annular lesions exhibiting a zonal histological pattern that includes a granulomatous response with giant cells at the annular rim and centrally a loss of elastic fibers or the presence of solar elastotic material. These conditions appear to form part of a spectrum. Some have used the term *annular elastolytic giant cell granuloma* as the group generic term,^{735,736} whereas others have used it for cases not associated with actinic damage and have retained the term *actinic granuloma* for those that do. The two entities are considered separately in the following discussion. The relationship, if any, of this group to the necrobiotic granulomas is controversial. Another lesion, granuloma multiforme, is also very similar clinically and histologically to these conditions and is discussed here.

Actinic granuloma

In 1975, O'Brien described annular skin lesions that occurred in sun-damaged skin and were characterized histologically by disappearance of solar elastotic fibers and, at the edge of the lesion, by a histiocytic and giant cell inflammatory reaction.^{732,737} His concept of a granulomatous response to solar elastosis was challenged by some⁷³⁸ and supported by others.^{739,740} Some believed that this lesion was granuloma annulare in sun-damaged skin.^{738,741} In support of O'Brien, similar changes have been described in association with solar elastosis in, or clinically resembling, pinguecula of the bulbar conjunctiva.⁷⁴²⁻⁷⁴⁴ Temporal arteritis may arise in association with actinic granuloma.⁷⁴⁵ Both conditions have been regarded as a response to actinically damaged elastic tissue.⁷⁴⁶

As initially described, actinic granuloma begins as single or grouped pink papules that evolve to annular lesions in sun-exposed regions of the neck, face, chest, and arms. A reticular pattern has been described in one case.⁷⁴⁷ Both sexes are affected equally, and most of the patients are 40 years of age or older. Alopecia resulted in one case.⁷⁴⁸ Solitary cases have been reported in association with relapsing polychondritis,⁷⁴⁹ molluscum contagiosum,⁷⁵⁰ and cutaneous amyloidosis.⁷⁵¹ Coexistence of actinic granuloma and an infiltrate of B-cell chronic lymphocytic leukemia has been described in one case.⁷⁵²

Actinic granuloma has been reported following prolonged sunbed usage⁷⁵³ and in association with prolonged doxycycline phototoxicity.⁷⁵⁴ Acitretin has been used to treat this condition.⁷⁵⁵

Histopathology

In annular lesions, the changes seen at the rim of the lesion differ from those in the center (Fig. 7.25). The dermis in the region of the rim is infiltrated by histiocytes, and there are many foreign body giant cells. The latter are applied to, and engulf, elastotic fibers (elastoclasia; Fig. 7.26). There is also a variable component of lymphocytes, plasma cells, and eosinophils. Within the central zone, there is complete or almost complete loss of both elastotic fibers and normal elastic fibers. The dermal collagen in this region is relatively normal or slightly increased.⁷⁵⁶ Asteroid bodies are sometimes present in giant cells. In some cases, mononuclear histiocytes may be more prominent than multinucleate giant cells, and occasionally tuberculoid granulomas form.⁷⁵⁷

A similar granulomatous response can occur in relation to some basal cell carcinomas and keratoacanthomas.⁷⁴⁰ Elastoclasia has also

Figure 7.25 Actinic granuloma. There are many foreign body giant cells in the central portion of the specimen arranged around elastotic fibers. Some fibers have been phagocytosed. This figure shows the zonal arrangement of the lesion, with a central loss of elastic fibers (right) and the patient's surrounding 'normal', elastotic dermis (left). (H&E)

Figure 7.26 Actinic granuloma. Multinucleate giant cells are engulfing elastotic fibers. (H&E)

been described in granuloma annulare,⁷⁵⁸ elastosis perforans serpiginosa, and other lesions occurring in sun-damaged skin.⁷³⁸ In these cases, elastoclasia may represent a secondary response to elastotic fibers that have been altered in some as yet unknown way by the primary process, whereas in actinic granuloma there is no obvious provoking cause. It has been suggested that there is a cell-mediated immune response to antigenic determinants on actinically altered elastotic fibers.⁷⁵⁹ Elastophagocytosis may also be seen in sun-protected skin in association with a variety of inflammatory conditions.⁷⁶⁰

Immunohistochemical studies have shown the presence of lysozyme in giant cells and a predominance of CD4⁺ T cells in the lymphocytic infiltrate.⁷⁵⁹ One ultrastructural study demonstrated both extracellular and intracellular digestion of elastotic fibers.⁷⁶¹

Annular elastolytic giant cell granuloma

As previously mentioned, this term has been used by some authors to describe all cases characterized by annular plaques with histological

evidence of elastophagocytosis by multinucleated giant cells.^{735,736,762-766} It is used here in a more restricted sense to exclude cases with severe solar elastosis, discussed here as actinic granuloma (discussed previously). They are both variants of elastolytic granulomas, the preferred group generic term.

It presents with multiple papules and annular plaques, sometimes spread over large parts of the body.^{767,768} Lesions are usually more extensive than in actinic granuloma. The plaques grow slowly. Covered areas are often involved. Infants are rarely affected; lesions resolved after the use of oral tranilast and topical pimecrolimus in one such infant.⁷⁶⁹

Annular elastolytic giant cell granuloma has been regarded as a prodromal stage of mid-dermal elastolysis.⁷⁷⁰ A recent report described sparing of striae distensae by the annular elastolytic lesions.⁷⁷¹ Association with malignancies has been reported occasionally; these include gastric carcinoma, prostate carcinoma, acute myelogenous leukemia, adult T-cell leukemia, and CD4⁺ small to medium-sized pleomorphic T-cell lymphoma.⁷⁷²⁻⁷⁷⁴ Despite some interesting circumstantial evidence, the relationship at this point appears to be coincidental. Favorable responses to hydroxychloroquine have been described.^{775,776}

Histopathology

There are granulomatous infiltrates, composed mostly of multinucleated giant cells exhibiting elastophagocytosis. There is no mucin, necrobiosis, or palisading. Rare lymphocytes are sometimes present. There is variable loss of elastic fibers; it is complete in late stages of the disease. One study showed strong expression of matrix metalloproteinase (MMP)-12 (also known as human macrophage metalloelastase) in the granulomas of annular elastolytic giant cell granuloma, possibly explaining the prominent elastolysis in these lesions, although this endopeptidase has also been found in the granulomas of granuloma annulare.⁷⁷⁴

Differential diagnosis

Because numerous granulomatous processes can demonstrate elastophagocytosis, actinic granuloma must be distinguished from *foreign body granulomas*, including those seen in association with ruptured follicles and cysts or accompanying keratinizing tumors. Therefore, granulomatous dermatoses should be examined carefully to exclude other etiologies. Polarization microscopy and special staining for organisms may be part of this evaluation. Two significant considerations in the differential diagnosis are *granuloma annulare* and *necrobiosis lipoidica*. This distinction is often possible because, unlike granuloma annulare and necrobiosis lipoidica, necrobiosis is not usually seen in annular elastolytic giant cell granuloma. The absence of increased dermal mucin also distinguishes most cases from granuloma annulare. In one study comparing actinic granuloma and granuloma annulare, the absence of elastotic material in the center of the lesions and the presence of scarring and giant cells with up to 12 nuclei were characteristic of actinic granuloma. By comparison, granuloma annulare was characterized by moderate amounts of elastotic material within granulomas, scarring was absent, and giant cells contained fewer nuclei.⁷⁷⁷ Similar findings have been made in two subsequent comparative studies,^{778,779} although in one of these studies, two cases with some features of granuloma annulare were described.⁷⁷⁹ In the case of lesions arising in sun-exposed skin, the best way to exclude these other granulomatous disorders may be to evaluate the lesion in the context of the surrounding connective tissue changes. This is made possible by an elliptical specimen through the annular border, allowing appreciation of a 'triple zone' arrangement: the previously described granulomatous changes representing the annular border, an absence of elastotic tissue in the central zone, and unaffected solar elastosis without inflammation in the periphery.

Atypical necrobiosis lipoidica

A condition characterized by annular lesions of the upper face and scalp has been called 'atypical necrobiosis lipoidica'.⁷³³ It occurs predominantly in females. The average age of onset is approximately 35 years. The lesions resolve spontaneously or persist for many years. Unlike necrobiosis lipoidica, they heal without scarring or alopecia. Some patients have necrobiosis lipoidica at other sites.

Lesions with similar clinical and histological features as those seen in atypical necrobiosis lipoidica have been described as Miescher's granuloma of the face.⁷³⁴ It has been suggested that both conditions represent actinic granulomas, although solar elastosis has not been a conspicuous feature in either.⁷³² The issue is further confused by reports of actinic granuloma with areas of necrobiosis.^{757,780}

Histopathology

These lesions are characterized by a central healing zone, in which there is loss of elastic tissue, and a peripheral raised edge. In the latter region, there is a lymphocytic and histiocytic dermal infiltrate that is distributed between collagen bundles. The infiltrate includes multinucleate giant cells, some of which contain asteroid bodies. Necrobiotic areas and increased dermal mucin have not been described.⁵²⁵

Granuloma multiforme

The granulomatous dermatitis, granuloma multiforme, was originally recognized because of its potential importance in the differential diagnosis of tuberculoid leprosy, which it resembles clinically and, to some extent, histologically.^{781,782} First reported in Nigeria, granuloma multiforme has also been reported in other central African countries, in Indonesia, and in India.^{781,783} Papular and annular lesions occur on exposed regions of the trunk and arms.⁷⁸⁴ Both sexes are affected, and most of the patients are age 40 years or older. There was a marked female predominance in one series.⁷⁸⁵ It has been suggested that this is a variant of granuloma annulare or necrobiosis lipoidica.⁷⁸⁵ Others consider it to be related to actinic granuloma.⁷³²

Histopathology

The zonal histology described in actinic granuloma is also seen in this condition (discussed previously). There is destruction of dermal elastic tissue, with mild fibrosis in the center of annular lesions. In the raised active edge of the lesion, there is a granulomatous reaction that includes histiocytes, multinucleate giant cells, lymphocytes, eosinophils, and plasma cells. Elastoclasia (elastic fiber phagocytosis by histiocytes) is seen in this region. Areas of necrobiosis have been described, surrounded by a palisaded rim of histiocytes, in the middle and upper dermis in the annular rim.⁷⁸⁵ Solar elastosis may occur in black-skinned people, but it is not clear whether it is present in the lesions of granuloma multiforme in black patients.⁷⁸⁶

In one series of cases, there was no evidence of fat within these lesions on special staining; mucin stains were inconclusive.⁷⁸⁵

ANNULAR GRANULOMATOUS LESIONS IN OCHRONOSIS

There have been several reports from South Africa of an annular eruption in ochronotic areas of the face in a group with hydroquinone-induced ochronosis.⁷⁸⁷⁻⁷⁸⁹ The lesions clinically resemble actinic granuloma and have a zonal appearance with a peripheral hyperpigmented ochronotic zone, an elevated rim, and a central hypopigmented area.

Table 7.3 Immunodeficiency disorders with cutaneous granulomas
Chronic granulomatous disease
X-linked hypogammaglobulinemia
Common variable immunodeficiency
Ataxia–telangiectasia
Nijmegen breakage syndrome
Severe combined immunodeficiency
Primary acquired hypogammaglobulinemia

Histopathology

Sections of the rim show a granulomatous response with histiocytes, epithelioid histiocytes, giant cells, lymphocytes, and plasma cells. Phagocytosis of ochronotic fibers is seen, with these fibers representing pigmented swollen collagen fibers. There may be epidermal changes associated with transepidermal elimination of ochronotic material in this region. The central zone has an atrophic epidermis with underlying absence of elastotic material and ochronotic fibers together with mild fibrosis. Elastophagocytosis was not seen despite the absence of elastotic material. Sarcoidal granulomas have also been reported in these lesions.⁷⁸⁷ It has been suggested that these lesions may represent a manifestation of sarcoidosis because some, but not all, cases are associated with systemic sarcoidosis.⁷⁸⁹

GRANULOMAS IN IMMUNODEFICIENCY DISORDERS

Granulomas of various types have been described in cutaneous lesions in persons with genetic and acquired immune deficiency disorders.⁷⁹⁰ They are listed in Table 7.3. In those with non-AIDS-related immune deficiency, various granuloma types have been described in cutaneous lesions.⁷⁹¹ Although, as might be expected, some are associated with a variety of infectious agents to which these patients are prone, many are not. Excellent reviews of the primary immunodeficiency disorders have been published.^{792,793}

In *chronic granulomatous disease*, despite the name, true granulomas are not common in cutaneous lesions. There are a variety of reports of suppurative granulomas with organisms, foreign body granulomas with and without organisms, and caseation necrosis.^{791,794–800} Carriers of X-linked chronic granulomatous disease (OMIM 306400) may present with lupus erythematosus-like lesions.⁸⁰¹ Several types of autosomal recessive chronic granulomatous disease occur (OMIM 233700, 233710, 233690). Caseating granulomas have been described in *X-linked infantile hypogammaglobulinemia* (OMIM 300300). Lymphocytes in the granulomas were almost exclusively of CD8 phenotype.⁸⁰² Sarcoid-like and caseating granulomas have been reported in lesions of *common variable immunodeficiency* (OMIM 240500).^{803–810} A recent example showed deep dermal/subcutaneous granulomatous infiltrates surrounded by a prominent lymphoplasmacytic infiltrate; no caseation or mucin deposition were identified, and stains and cultures were negative for organisms.⁸¹¹ This disease, which has multiple phenotypes, is the most commonly diagnosed primary immunodeficiency disease in adults, after selective IgA deficiency.⁸¹² Onset of symptoms is not until the second or third decade of life.^{812,813} It results from a dysfunction of B-cell differentiation resulting from mutations in the *TNFRSF13B* gene on chromosome 17p11.2.⁸¹⁴ TNF- α is elevated in this condition, and specific inhibition of this cytokine has been successful in moderating the disease.⁸¹⁵ Cutaneous lesions in *ataxia–telangiectasia* (OMIM 208900) have contained necrobiotic and tuberculoid granulomas.^{806,816–818} Sarcoid-

like granulomas have also been reported in this condition and in the related Nijmegen breakage syndrome (OMIM 251260) (see previous discussion of sarcoidosis).⁸¹⁹ Necrobiotic and tuberculoid granulomas have also been reported in *combined immunodeficiency*, an old term for a heterogeneous group of conditions.⁸²⁰ Sarcoidosis with typical granulomas may also be associated with combined immunodeficiency.⁸²¹ There is a lower CD4⁺:CD8⁺ ratio in the sarcoidal granulomas of the immunodeficiency group than in the granulomas of sarcoidosis.⁸²² In one case of *primary acquired agammaglobulinemia*, noncaseating granulomas were described.⁸²³ Two neonates with perforating neutrophilic and granulomatous dermatitis have been reported. This pattern was said to be a clue to an immunodeficiency that took the form of agammaglobulinemia.⁸²⁴

The association of granuloma annulare and HIV infection has been described previously.⁸²⁵ Occasionally, granulomas with no apparent infectious agent are seen in the papular lesions of AIDS. As might be expected because of low levels of CD4⁺ T lymphocytes, organisms associated with granulomas in immunodeficient individuals usually proliferate without granuloma formation or with poor granuloma formation.⁸²⁶ However, there are reports of granuloma formation in Kveim tests in HIV-positive individuals,⁸²⁷ and granuloma formation without organism proliferation has been described in a series of patients with both borderline tuberculoid leprosy and HIV infection,⁸²⁸ suggesting that factors other than CD4⁺ T lymphocytes are involved in granuloma formation. A study of foreign body reactions to ruptured cysts in HIV-infected individuals showed some differences compared to the reaction in the immunocompetent. These included little tendency to form giant cells, macrophages phagocytosing lymphoid cells, and increased numbers of mast cells and eosinophils.⁸²⁹

INTERSTITIAL GRANULOMATOUS DERMATITIS

Interstitial granulomatous dermatitis is the preferred designation for a clinically heterogeneous entity that may present as linear cords (the ‘rope sign’), papules, or plaques.^{830–839} The cords tend to be skin-colored and situated on the lateral trunk, whereas the papules are skin-colored or erythematous with umbilication, crusting, or perforation in some lesions.⁸⁴⁰ The plaques, which are asymptomatic, are erythematous to violaceous and symmetrically distributed.^{836,841}

A variety of systemic illnesses are associated with these lesions, particularly rheumatoid arthritis, although tests for rheumatoid factor are not always positive.⁸⁴² Some patients present with arthralgias. The term ‘*interstitial granulomatous dermatitis with arthritis*’ is often used for these cases to highlight the importance of the accompanying joint disease. Other terms used include ‘*rheumatoid papules*’ and ‘*palisaded neutrophilic and granulomatous dermatitis*’.^{584,831,843,844} Autoimmune thyroiditis, autoimmune hepatitis, systemic sclerosis,⁸⁴⁵ systemic lupus erythematosus, chronic uveitis,⁸⁴⁶ antiphospholipid syndrome, vasculitis, sarcoidosis,^{847,848} relapsing polychondritis,⁸⁴⁹ chronic inflammatory demyelinating polyneuropathy,⁸⁵⁰ type 1 diabetes mellitus,⁸⁵¹ immunodeficiency, polyfibromatosis, metastatic carcinoma, lymphoma, and leukemia have been associated with these cutaneous lesions.^{824,831,833,834,852–858} Various infections have been associated with interstitial granulomatous dermatitis or a pattern similar to it. They include HIV infection, fifth disease of parvovirus B19 infection, Lyme disease, hepatitis C, Epstein–Barr and *Mycoplasma* infection, and adjacent to lesions of molluscum contagiosum.^{417,859} It has also been associated with pulmonary coccidioidomycosis.⁸⁶⁰ Lesions with similar microscopic features can also occur without an identifiable underlying disorder.⁸⁶¹ The papular eruption developing in some patients with rheumatoid disease treated with methotrexate has some histological similarities.

The etiology is unknown, but the clinical associations strongly support immune complex deposition.⁸³¹

Figure 7.27 Interstitial granulomatous dermatitis in a patient with rheumatoid arthritis. (A) The lower half of the dermis is thickened and involved. (B) Individual collagen bundles have a palisade of histiocytes and lymphocytes. Eosinophils are not obvious in this field. (H&E)

Treatment of the autoimmune-associated cases is usually with systemic corticosteroids. Infliximab has also been used,⁸⁶² as have ustekinumab⁸⁶³ and tocilizumab, a monoclonal antibody against the IL-6 receptor.⁸⁶⁴ Dapsone was successful in a patient with rheumatoid papules⁸⁶⁵ and in a patient who had interstitial granulomatous dermatitis without an underlying disorder.⁸⁶¹

Histopathology^{831,833,852}

There is some resemblance to the changes described in 1983 by Finan and Winkelmann as ‘cutaneous extravascular necrotizing granuloma (Churg–Strauss granuloma)’.⁸⁵² Different patterns have been described, but they probably represent different stages or variable expression of the disease. One pattern resembles incomplete granuloma annulare with an interstitial and perivascular dermal infiltrate of neutrophils, neutrophil fragments, histiocytes, and lymphocytes. Eosinophils may be present. In some cases, there is a leukocytoclastic vasculitis. Another variation is the presence of a palisade of histiocytes and lymphocytes around a central zone of numerous neutrophils.⁸⁶⁶ Dermal collagen appears somewhat basophilic, possibly from nucleic acid staining. In the second pattern, there are small granulomas composed of a palisade

of histiocytes about a small number of basophilic collagen fibers (Fig. 7.27). Rosettes of histiocytes may surround empty spaces, within which are degenerated collagen bundles (the ‘floating sign’).⁸⁶⁷ There may be central neutrophils and neutrophil fragments. Histiocyte pseudorosettes have been described in the cases of cutaneous borreliosis.⁸⁵⁹ Changes may involve the full thickness of the dermis and sometimes the superficial subcutis or primarily the lower dermis.⁸³⁰ Accentuation of the process in the lower dermis is a characteristic feature. Some authors describe mucin within and around the granulomas, but there is less mucin than occurs in granuloma annulare. Older lesions may have dermal fibrosis.

It is claimed by one group that the early lesions differ from conventional leukocytoclastic vasculitis by having broader fibrin cuffs about vessels, fewer extravasated erythrocytes, and more neutrophils and neutrophil dust in the dermis.⁸³¹ There are more interstitial neutrophils in the dermis than are typically seen in either the incomplete or granulomatous forms of granuloma annulare. The author has seen many cases with relatively sparse neutrophils and eosinophils.

Some lesions have surface necrosis, scale crust, or epidermal hyperplasia associated with perforation.

Immunofluorescence studies have demonstrated C3, IgM, and fibrinogen in dermal blood vessels in some cases.^{833,852}

Differential diagnosis

Interstitial granulomatous dermatitis sometimes has a close resemblance to the interstitial form of *granuloma annulare*, and this is probably the chief differential diagnostic consideration. Both show interstitial dermal infiltration by macrophages, deposits of mucin, and scattered eosinophils. However, the interstitial infiltrates of granuloma annulare tend to be focal, whereas changes of interstitial granulomatous dermatitis tend to be more diffuse, producing the low-power impression of a ‘busy’ dermis. Neutrophils constitute an important component of interstitial granulomatous dermatitis of systemic disease (although they are not always conspicuous) but are generally not observed in uncomplicated interstitial granuloma annulare. Mucin can be seen in both, but deposits tend to be focally more intense in interstitial granuloma annulare, and colloidal iron staining will more often show accentuated mucinous deposits within areas of interstitial inflammation in that disease. Although disorganization of collagen bundles is often seen in granuloma annulare, the finding of macrophages surrounding isolated, basophilic collagen bundles is more consistent with interstitial granulomatous dermatitis.

INTERSTITIAL GRANULOMATOUS DRUG REACTION

Twenty cases were reported under the title ‘interstitial granulomatous drug reaction’ in 1998.⁸⁶⁸ It has since received scant attention.⁸⁶⁹ Some dermatopathologists have expressed doubts about its validity. In the author’s experience of more than 25 cases, the clinical and histological features have been consistent with those originally described.

Clinically, the lesions are erythematous to violaceous, nonpruritic plaques, often having an annular configuration. There may be one or several plaques or widespread lesions. The inner aspects of the arms, medial thighs, intertriginous areas, and the trunk are sites of predilection. The provisional clinical diagnosis usually includes such entities as granuloma annulare, mycosis fungoides, lupus erythematosus, or erythema annulare centrifugum. Erythema nodosum-like lesions have also been described.⁸⁷⁰ A drug reaction is not usually suspected.⁸⁶⁸

Drugs implicated in the etiology of this eruption include calcium channel blockers, β -blockers, angiotensin-converting enzyme inhibitors, furosemide, sennoside, lipid-lowering agents, antihistamines, a Chinese herbal medication, anti-TNF- α therapy, intravenous ganciclovir, strontium ranelate, anticonvulsants,^{868,871–877} allopurinol,⁸⁷⁸ and sorafenib.⁸⁷⁹ Drug reactions microscopically described as palisaded neutrophilic and granulomatous dermatitis have been attributed to adalimumab⁸⁸⁰ and allopurinol.⁸⁸¹ Patients are often on one or more of these drugs. Soy products have also been implicated.⁸⁸² Several personally studied cases have used the combination of a thiazide diuretic and hormone replacement therapy. Magro *et al.* reported 10 cases of drug-associated pseudolymphoma resembling granulomatous mycosis fungoides and proposed that this be considered a subtype of the interstitial granulomatous drug reaction.⁸⁸³ Drugs that may produce this pattern of inflammation are listed in Table 7.4. The lesions resolve on cessation of the drug(s).

A similar pattern has been described as a localized reaction at the site of injection of the HIV-1 fusion inhibitor, enfuvirtide.⁸⁸⁴ In some areas, the lesions resembled a hypersensitivity reaction.

Histopathology⁸⁶⁸

The low-power impression is of the incomplete form of granuloma annulare (see p. 200) because of the hypercellular (‘busy’) dermis

Table 7.4 Drugs associated with an interstitial granulomatous pattern	
ACE inhibitors	Furosemide
Adalimumab	Ganciclovir (IV)
Allopurinol	‘Herbal medicine’
Anticonvulsants	Sorafenib
Antidepressants	Soy products
Antihistamines	Statins
Anti-TNF- α therapy	Strontium ranelate
β -Blockers	Thiazides + HRT
Enfuvirtide injection site	

resulting from a diffuse interstitial infiltrate of lymphocytes and histiocytes with piecemeal fragmentation of collagen and elastic fibers (Fig. 7.28). The lymphocytes appear activated and mildly atypical. There may be focal epidermotropism. A few multinucleate giant cells may be present, but they are not a conspicuous feature. Eosinophils are usually present in small numbers. Flame figures have been described.⁸⁷³ Red cell extravasation is sometimes present. Mucin deposition is variable.

Another feature that is usually present is a mild interface (lichenoid) reaction with vacuolar change and occasional apoptotic keratinocytes. These changes are absent in some cases, but the lack of degenerated collagen may assist in making the diagnosis in such cases.⁸⁷³

Differential diagnosis

This drug reaction differs from granuloma annulare by the absence of any significant necrobiosis, the general predominance of lymphocytes over histiocytes, and the presence of eosinophils and interface change. Nevertheless, cases occur with overlap features between interstitial granulomatous dermatitis, a drug variant of this, and granuloma annulare (Fig. 7.29). It differs from interstitial granulomatous dermatitis (discussed previously) by the lack of deep dermal accentuation and the less conspicuous rimming of isolated collagen bundles by histiocytes. Although a lichenoid tissue reaction is more commonly associated with the interstitial granulomatous drug reaction, it has been reported in interstitial granulomatous dermatitis.⁸⁶⁷

SUPERANTIGEN ID REACTION

This term was given by Magro and Crowson to a cutaneous reaction pattern indicative of infection by reactive arthropathy-associated microbial pathogens.⁸⁸⁵ It was regarded as an immunological response to extracutaneous or systemic infections. Among the implicated pathogens were cytomegalovirus, parvovirus B19, *Streptococcus*, *Mycoplasma*, *Klebsiella*, and *B. borgdorferi*. The cases of interstitial granulomatous dermatitis associated with these infections may well have been examples of this concept.

There was a striking female predominance. The skin lesions clinically resembled Sweet’s syndrome, erythema multiforme, and/or erythema nodosum.⁸⁸⁵

Histopathology

The changes had some resemblance to an interstitial granulomatous drug reaction, combining a focal lymphocytic interface (lichenoid) pattern with a diffuse interstitial histiocytic infiltrate and a perivascular and intramural vascular reaction, often accompanied by fibrin deposition.⁸⁸⁵ Eosinophils, spongiosis, and papillary dermal edema were sometimes present.

Figure 7.28 (A) Interstitial granulomatous drug reaction. (B) There is a 'busy' (hypercellular) dermis mimicking the incomplete (interstitial) type of granuloma annulare. (H&E)

GRANULOMATOUS T-CELL LYMPHOMAS

Rare cases of mycosis fungoides and Sézary syndrome have a granulomatous infiltrate in the dermis (see p. 1177).⁸⁸⁶ Granulomas may be a component of the lymphoma, in the circumstances just mentioned, or be a nonspecific manifestation of the lymphomatous process.²⁰ Granulomas are also present in granulomatous slack skin,⁸⁸⁷⁻⁸⁹⁰ a variant of T-cell lymphoma (see p. 1181). In these conditions, phagocytosis of elastic fibers and lymphocytes may occur. Necrobiosis (collagenolysis) was present in one case of granulomatous slack skin.⁸⁹¹

COMBINED GRANULOMATOUS AND LICHENOID PATTERN

Magro and colleagues have been responsible for elucidating this distinctive pattern of cutaneous inflammation.^{610,892} It has been associated with a number of disorders, including underlying hepatobiliary disease, rheumatoid arthritis, endocrinopathies, Crohn's disease, and various infections that include post-herpetic reactions, HIV infection, and, rarely, nontuberculous (atypical) mycobacterial infections.⁶¹⁰

Figure 7.29 (A) Drug reaction. There are mixed features between interstitial granulomatous drug reaction and **(B)** granuloma annulare. (H&E)

Granulomas can also be found in various lichenoid (interface) disorders, such as lichen planus, lichen nitidus, lichen striatus, and lichenoid drug reactions. Drugs that can give this combined pattern are shown in [Table 7.5](#). Erythropoietin, used in the treatment of myeloma, has also produced dual tissue reactions.⁸⁹³

Both epithelioid granulomas of tuberculoid type and a lichenoid pattern of graft-versus-host disease were present in a post-transplant patient who presented with widespread erythematous macules and brownish papules on the trunk and extremities.⁸⁹⁴ The nature of the process was not elucidated.

Table 7.5 Drugs producing a combined lichenoid/granulomatous pattern	
ACE inhibitors	Erythropoietin
Allopurinol	Oxacillin
Antihistamines	Quinine
Atenolol	Statins
Cimetidine	Sulfur-containing drugs
Diclofenac	Tetracyclines

INTRODUCTION

Cutaneous blood supply

The skin is supplied by small segmental arteries that may reach the skin directly or after supplying the underlying muscle and soft tissues en route. These vessels branch to supply the subcutis with a meshwork of arteries and arterioles. In the dermis, there is a *deep (lower) horizontal plexus*, situated near the interface with the subcutis, and a *superficial (upper) horizontal plexus*, at the junction of the papillary and reticular dermis. The two plexuses are joined by vertically oriented arterioles. These interconnecting arterioles also give rise to vessels that form an arborizing plexus around the hair follicles. The sweat gland plexus of vessels may also arise from the vertical arterioles or from arteries in the subcutis.

The superficial horizontal plexus is a band-like network of anastomosing small arterioles and postcapillary venules, connected by a capillary network. The bulk of the microcirculation of the skin resides in this plexus and the capillary loops that form from it and pass into the dermal papillae. The postcapillary venules are the important functional sites for disease processes in the skin. For example, they represent the site of immune complex deposition in acute vasculitis, the site of vascular permeability in urticaria, and an area for leukocyte recruitment and diapedesis in vasculitis.

The *arterioles* in the superficial plexus have a homogeneous basement membrane, a discontinuous subendothelial elastic lamina, and one or two layers of smooth muscle cells (in contrast to arterioles in the deep plexus, which have four or five layers). The capillary wall contains a basement membrane that changes from homogeneous to multilayered as it changes from an *arteriolar capillary* to a venous capillary. The *postcapillary venule* is surrounded by veil cells rather than the smooth muscle cells seen in arterioles. The venules drain into large veins that accompany the vertically oriented arterioles. At the dermal-subcutaneous junction, there are collecting veins with two cusped valves that are oriented to prevent the retrograde flow of blood.¹

In addition to the vessels listed previously, there are *arteriovenous anastomoses* (shunts) that bypass the capillary network. They play a role in thermoregulation. A special form of arteriovenous shunt, occurring in the periphery, is the *glomus apparatus*. The glomus is composed of an endothelial-lined channel surrounded by cuboidal glomus cells; it has a rich nerve supply.

The dermal lymphatic network has a similar pattern of distribution to that of the blood supply.

At a functional level, the endothelial adherens junction complex is an important mechanism in the control of leukocyte and macromolecule transmigration. The adherens junction is formed by transmembrane molecules of the cadherin family linking to catenins, which anchor the adhesion plaque to the cytoskeleton of the endothelial cell.² The cadherin is cell-type specific and in the vessel is known as vascular endothelial (VE)-cadherin.² Interestingly, the VE-cadherin knockout mouse dies during embryonic development, indicating the importance of this substance in organogenesis.²

Categorization of diseases of blood vessels

Diseases of cutaneous blood vessels are an important cause of morbidity. In the case of the vasculitides, mortality may occasionally result. Blood vessels have a limited number of ways in which they can react to insults of various kinds, resulting in considerable morphological overlap between the various clinical syndromes that have been described.

The broad classifications used in this chapter are morphologically rather than etiologically based because this is the most practical scheme to follow when confronted with a biopsy.

Excluding tumors and telangiectases, which are discussed in Chapter 38, there are six major groups of vascular diseases:

- Non-inflammatory purpuras
- Vascular occlusive diseases
- Urticarias
- Vasculitis
- Neutrophilic dermatoses
- Miscellaneous.

The *non-inflammatory purpuras* are characterized by the extravasation of erythrocytes into the dermis. There is no inflammation or occlusion of blood vessels.

The *vascular occlusive diseases* exhibit narrowing or obliteration of the lumina of small vessels by fibrin or platelet thrombi, cryoglobulins, cholesterol, or other material. Purpura and sometimes ulceration and necrosis may be clinical features of this group.

The *urticarias* involve the leakage of plasma and some cells from dermal vessels. Some of the urticarias have overlapping features with the vasculitides, further justification for their inclusion in this chapter.

In *vasculitis*, there is inflammation of the walls of blood vessels. In subsiding lesions, there may only be an inflammatory infiltrate in close contact with vessel walls. The vasculitides are subclassified on the basis of the inflammatory process into acute, chronic lymphocytic, and granulomatous forms. Fibrin-platelet thrombi may sometimes form, particularly in acute vasculitis, leading to some overlap with the vascular occlusive diseases.

The *neutrophilic dermatoses* are a group of conditions in which there is a prominent dermal infiltrate of neutrophils, but usually without the fibrinoid necrosis of vessel walls that typifies acute (leukocytoclastic) vasculitis.

The *miscellaneous group* of vascular disorders includes the capillary leak syndrome, vascular calcification, collagenous vasculopathy, pericapillary fibrin cuffs, vascular aneurysms, erythralgia, and cutaneous necrosis and ulceration.

NON-INFLAMMATORY PURPURAS

Purpura is hemorrhage into the skin. Clinically, this may take the form of small lesions less than 3 mm in diameter (petechiae) or larger areas known as ecchymoses. There is a predilection for the limbs. The numerous causes of purpura may be broadly grouped into defects of blood vessels, platelets, or coagulation factors.^{3,4}

At the histopathological level, purpuras are characterized by an extravasation of red blood cells into the dermis from small cutaneous vessels. If the purpura is chronic or recurrent, hemosiderin or hematoidin pigment may be present.^{5,6} Purpuras have traditionally been divided into an inflammatory group (vasculitis) and a non-inflammatory group when there is no inflammation of vessel walls.

The non-inflammatory purpuras include idiopathic thrombocytopenic purpura, senile purpura, the autoerythrocyte sensitization syndrome (psychogenic purpura), traumatic (including factitious) purpura,⁷⁻¹¹ and drug purpuras.¹²

The **autoerythrocyte sensitization syndrome** (Gardner-Diamond syndrome) is an uncommon bruising disorder affecting predominantly women with emotional instability.¹³⁻¹⁷ It is characterized by periodic, painful ecchymoses giving bruise-like areas mostly on the upper and lower limbs. Pain or a prickly sensation may precede the ecchymoses.¹⁸ The diagnosis can be confirmed by the intradermal injection of autologous whole blood (autoerythrocyte sensitization test), which will reproduce the tender bruises in this syndrome.^{17,19} Painful bruising in a bizarre, almost factitious arrangement has been reported in a male traveler. He does not appear to have this syndrome.²⁰

Sickle-cell disease is an unusual cause of purpura.²¹ Only senile purpura is considered in further detail in this volume.

Figure 8.1 Non-inflammatory purpura. This is senile purpura. (H&E)

SENILE PURPURA

Senile purpura is a common form of non-inflammatory purpura that occurs on the extensor surfaces of the forearms and hands of elderly individuals.^{22,23} Usually, large ecchymoses are present. It has been suggested that the bleeding results from minor shearing injuries to poorly supported cutaneous vessels. Senile purpura tends to persist longer than other forms of purpura, indicating slower removal or breakdown of the erythrocytes. Furthermore, senile purpura does not usually show the color changes of bruising, as seen in purpura of other causes.

Histopathology

Senile purpura is characterized by extravasation of red blood cells into the dermis (Fig. 8.1). This is most marked in the upper dermis and in a perivascular location. There is also marked solar elastosis and often some thinning of the dermis with atrophy of collagen bundles.

VASCULAR OCCLUSIVE DISEASES

Occlusion of cutaneous blood vessels is quite uncommon. The clinical picture that results is varied. It may include purpura, livedo reticularis,^{24–26} erythromelalgia, ulceration, or infarction. Cutaneous infarction only occurs when numerous vessels in the lower dermis and subcutis are occluded. Because livedo reticularis is a clinical feature of some of the diseases discussed in this section, it is considered first.

Livedo reticularis

Livedo reticularis consists of macular, violaceous, connecting rings that form a net-like pattern.²⁷ In most cases, it is a completely benign finding related to cold exposure. It results from increased visibility of the venous plexus that can result from venodilation often caused by deoxygenation of blood in the venous plexus. Cold results in deoxygenation by vasospasm leading to venodilation.²⁷ Most of the diseases discussed as venoocclusive diseases can produce secondary livedo reticularis.

In addition other vascular diseases, drugs, infections, and neurological and metabolic diseases can be associated with livedo reticularis.^{28,29} The drugs that can result in livedo reticularis include amantadine,³⁰

minocycline, gemcitabine, heparin, and interferon therapy.^{27,31} Laser-assisted hair removal may result in a reticulate erythema resembling livedo reticularis.³² Almost 100 different diseases and drugs that can cause livedo reticularis are listed in the excellent review of this subject by Gibbs *et al.* in 2005.²⁷

Nicolau's syndrome (livedo-like dermatitis, embolia cutis medicamentosa) has painful areas resembling livedo reticularis at the edge of hemorrhagic aseptic necrosis. It has followed the intramuscular injection of bismuth salts, nonsteroidal anti-inflammatory drugs (NSAIDs),^{33–35} penicillin,³⁶ cyanocobalamin,³⁶ piroxicam,³⁷ thiocolchicoside,³⁸ and diphtheria–tetanus–pertussis (DTP) vaccine.^{39,40} Retiform purpura in plaques (RPP) is a morphological sign that differs from livedo reticularis by the presence in RPP of ischemia-related hemorrhage around a vessel, prior to its complete occlusion.⁴¹

Complete or partial occlusion of cutaneous vessels usually results from the lodgment of fibrin-platelet thrombi. Other causes include platelet-rich thrombi in thrombocythemia and thrombotic thrombocytopenic purpura, cryoglobulins in cryoglobulinemia, cholesterol in atheromatous emboli, swollen endothelial cells containing numerous acid-fast bacilli in Lucio's phenomenon of leprosy, fungi in mucormycosis,⁴² and fibrous tissue producing intimal thickening in endarteritis obliterans.⁴³

Excluding vasculitis, which is considered later, vascular occlusion may be seen in the following circumstances:

- Protein C and protein S deficiencies
- Prothrombin gene mutations
- Warfarin necrosis
- Atrophie blanche (livedoid vasculopathy)
- Disseminated intravascular coagulation
- Purpura fulminans
- Thrombotic thrombocytopenic purpura
- Thrombocythemia
- Cryoglobulinemia
- Cholesterol and other types of embolism
- Antiphospholipid syndrome
- Factor V Leiden mutation
- Sneddon's syndrome
- CADASIL
- Miscellaneous conditions.

PROTEIN C AND PROTEIN S DEFICIENCIES

Because deficiencies, congenital or acquired, of protein C or protein S underlie some of the diseases considered in this section, they are considered first. Because protein S is a cofactor of activated protein C, they are discussed together.

Protein C, a vitamin K-dependent plasma glycoprotein, has, when activated, an important anticoagulant role by destroying factors Va and VIII.^{44,45} Congenital protein C deficiency (OMIM 176860) is usually inherited as an autosomal dominant trait, although a few autosomal recessive cases have been described. It results from mutations in the protein C (*PROC*) gene on chromosome 2q13–q14. Patients with a homozygous deficiency usually present with purpura fulminans (see p. 223) in childhood.^{46,47} Heterozygous deficiency predisposes to venous thrombosis in adulthood or warfarin necrosis (see p. 222).^{48,49} Skin necrosis is another manifestation of this deficiency.^{45,50} Acquired deficiencies have resulted from infections,⁵¹ chronic ulcerative colitis,⁵² and anticoagulant therapy.⁵³ Acquired deficiencies can also predispose to purpura fulminans⁵² and to warfarin necrosis.⁵⁴

Protein S is another vitamin K-dependent protein that serves as a cofactor for activated protein C. Protein S deficiency (OMIM 176880) can predispose to the same conditions as protein C deficiency,⁵⁵

including warfarin necrosis.⁵⁶ It is caused by a mutation in the protein S (*PROS1*) gene on 3p11.1–q11.2. Protein S appears also to have functions outside the coagulation pathway.

PROTHROMBIN GENE MUTATIONS

The 20210G-A mutation in the prothrombin gene (coagulation factor II; OMIM *176930) is found in 0.7–2.6% of the population and in 4–8% of patients presenting with first-episode venous thrombosis.⁵⁷ It leads to hyperprothrombinemia. It may occur in association with other genetic disorders of the coagulation pathway, particularly the factor V Leiden mutation, which is also very common in the community. Both mutations probably occurred more than 20,000 years ago, and both appear to have provided selective evolutionary advantages.⁵⁸ It has been reported in association with atrophie blanche (livedoid vasculopathy).⁵⁷

WARFARIN NECROSIS

Cutaneous infarction is a rare, unpredictable complication of anticoagulant therapy with the coumarin derivative warfarin sodium. It has a predilection for fatty areas such as the thighs, buttocks, and breasts of obese, middle-aged women.^{59,60} Lesions usually develop several days after the commencement of therapy. Late-onset lesions can be difficult to diagnose.⁶¹ There are well-defined ecchymotic changes that rapidly progress to blistering and necrosis. Purpuric⁶² and linear lesions⁶³ have been reported.

Warfarin necrosis is related to low levels of protein C, a vitamin K-dependent plasma protein with potent anticoagulant properties.⁴⁴ This deficiency in protein C may be induced by the anticoagulant therapy⁵³ or pre-exist in those who are heterozygous for protein C deficiency.^{46,48} It can also result from protein S deficiency and a mutation in the methylenetetrahydrofolate reductase (*MTHFR*) gene (OMIM *607093).⁵⁶ Warfarin necrosis has also been associated with the factor V Leiden mutation, indicating that several closely related factors may contribute to warfarin-induced necrosis.^{64,65} Acute renal failure was thought to be the cause in one case.⁴⁹ Rarely, widespread disseminated intravascular coagulation is associated with warfarin therapy.⁶⁶ Warfarin necrosis has been successfully treated with human protein C concentrate.⁶⁷

Various reactions, including hemorrhagic bullae, urticaria, necrosis due to thrombosis of dermal capillary vessels, and eczematous lesions, may occur at sites of **subcutaneous heparin injections** or at sites distant from the injection site.^{68,69} The mechanism of formation of the hemorrhagic bullae is unknown.⁶⁸ It is not related to warfarin necrosis in any way, although in a given case heparin-induced thrombocytopenia can be associated with warfarin necrosis.^{70,71} Widespread skin necrosis may also occur due to thrombosis of dermal vessels in patients receiving heparin therapy. The incidence of this complication varies between 1% and 3% for a 1-week course of intravenous heparin therapy. It is often due to the presence of antibodies directed against heparin-platelet factor 4.^{72,73}

Histopathology

Fibrin-platelet thrombi are present in venules and arterioles in the deep dermis and subcutis. There is variable hemorrhage and subsequently the development of infarction. Large areas of the skin may be involved.

ATROPHIE BLANCHE (LIVEDOID VASCULOPATHY)

Although previously considered to be caused by a vasculitis, atrophie blanche (white atrophy) is best regarded as a manifestation of a

thrombogenic vasculopathy in which occlusion of small dermal vessels by fibrin thrombi is the primary event.^{74–76} It appears to result from decreased fibrinolytic activity of the blood with defective release of tissue plasminogen activator from vessel walls.^{77–81} The platelets usually show an increased tendency to aggregate. An elevated level of fibrinopeptide A, suggestive of a thrombogenic state, has been found in patients with this condition.⁷⁵ Several cases with a lupus-type anticoagulant and an increased level of anticardiolipin antibodies have been reported.⁸² This abnormality can alter fibrinolytic activity. Other associations of atrophie blanche include protein C deficiency,⁸³ factor V Leiden mutation,^{84,85} prothrombin mutations,⁸⁶ IgM antiphosphatidylserine–prothrombin complex antibody,⁸⁷ plasminogen activator inhibitor-1 promoter mutations (OMIM *173360),⁸⁸ antithrombin III deficiency,⁸⁹ methylenetetrahydrofolate reductase mutations (*MTHFR*; OMIM *607093),^{90,91} homocysteinemia (OMIM 603174),⁹² and essential cryoglobulinemia^{93,94} – all of which can contribute to a hypercoagulable condition.⁹⁵

Atrophie blanche (synonyms: livedoid vasculopathy, livedo vasculitis, segmental hyalinizing vasculitis, and painful purpuric ulcers with reticular patterning on the lower extremities (PURPLE))⁹⁶ is characterized by the development of telangiectatic, purpuric papules and plaques leading to the formation of small crusted ulcers, which heal after many months to leave white atrophic stellate scars.^{97,98} The ulcers are painful and recurrent. Sometimes they are large and slow to heal. The lower parts of the legs, especially the ankles and the dorsum of the feet, are usually involved, although rarely the extensor surfaces of the arms below the elbows can be affected. Many patients also have livedo reticularis,⁹⁹ whereas some may have systemic diseases such as scleroderma, systemic lupus erythematosus (SLE), and cryoglobulinemia.¹⁰⁰ The disorder has a predilection for middle-aged females, but all ages may be affected.⁹⁷

Atrophie blanche-like scarring can occur uncommonly after pulsed dye laser treatment of vascular malformations.¹⁰¹

Therapies that have been used with varying degrees of success include antiplatelet drugs and antithrombotic drugs,¹⁰² dapsone, nicotinic acid, intravenous immunoglobulin,^{103,104} PUVA therapy,¹⁰⁵ danazol, hyperbaric oxygen,¹⁰⁶ warfarin therapy,⁹⁴ and, recently, amelogenin (enamel matrix protein) ECM protein.¹⁰⁷ Callen published a therapeutic 'ladder' for the management of this condition.¹⁰²

Histopathology¹⁰⁸

The changes will depend on the age of the lesion that is biopsied. The primary event is the formation of hyaline thrombi in the lumen of small vessels in the upper and mid dermis.^{95,100} Rarely, deeper vessels are involved.⁹⁷ Polyarteritis nodosa is rarely present.¹⁰⁹ Fibrinoid material is also present in the walls of these blood vessels and in perivascular stroma (**Fig. 8.2**). This material is PAS positive and diastase resistant. There is usually infarction of the superficial dermis, often with a small area of ulceration. Sometimes a thin parakeratotic layer is present overlying infarcted or atrophic epidermis. The epidermis adjacent to the ulceration may be spongiotic. A sparse perivascular lymphocytic infiltrate may be present, but there is no vasculitis. Neutrophils, if present, are usually sparse and confined to the infarcted upper dermis and ulcer base. There are often extravasated red cells in the upper dermis. Small blood vessels are often increased in the adjacent papillary dermis, but this is a common feature in biopsies from the lower parts of the legs and is therefore of no diagnostic value.

In older lesions, there is thickening and hyalinization of vessels in the dermis with some endothelial cell edema and proliferation. Fibrinoid material may also be present in vessel walls. Note that fibrinoid material is almost invariably present in blood vessels in the base of ulcers, of many different causes, on the lower legs. In atrophie blanche, the involved vessels are not only in the base of any ulcer but also may be found at a distance beyond this. In even later lesions, there is dermal

Figure 8.2 (A) Atrophie blanche in the pre-ulcerative stage. (B) Fibrinoid material is present in the walls of small blood vessels in the upper dermis. (H&E)

sclerosis and scarring with some dilated lymphatics and epidermal atrophy. There may be a small amount of hemosiderin in the upper dermis. Because these areas may become involved again, it is possible to find dermal sclerosis in some early lesions.

Immunofluorescence will demonstrate fibrin in vessel walls in early lesions, whereas in later stages there are also immunoglobulins and complement components in broad bands about vessel walls.^{74,110}

Electron microscopy

This has confirmed the presence of luminal fibrin deposition with subsequent endothelial damage.⁷⁴

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is an acquired disorder in which activation of the coagulation system leads to the formation of thrombi in the microcirculation of many tissues and organs.^{111,112} As a consequence of the consumption of platelets and of fibrin and other factors during the coagulation process, hemorrhagic manifestations also occur. DIC may complicate infections, various neoplasms, certain obstetric incidents, massive tissue injury such as burns, and miscellaneous conditions such as liver disease, snake bite, and vasculitis.¹¹¹

Cutaneous changes are present in approximately 70% of cases, and these may be the initial manifestations of DIC.^{113,114} Petechiae,

Figure 8.3 Disseminated intravascular coagulation. Small vessels in the upper dermis contain fibrin-platelet thrombi. (H&E)

ecchymoses, hemorrhagic bullae, purpura fulminans, bleeding from wounds, acral cyanosis, and frank gangrene have all been recorded.^{113,115,116}

The formation of thrombi appears to be a consequence of the release of thromboplastins into the circulation and/or widespread injury to endothelial cells. Decreased levels of protein C have been reported; the level returns to normal with clinical recovery.¹¹⁷

Histopathology¹¹⁴

In early lesions, fibrin thrombi are present in capillaries and venules of the papillary dermis and occasionally in vessels in the reticular dermis and subcutis (Fig. 8.3). Hemorrhage is also present, but there is no vasculitis or inflammation.

In older lesions, of 2 or 3 days' duration, there may be epidermal necrosis, subepidermal bullae, extensive hemorrhage, and patchy necrosis of eccrine glands, the pilosebaceous apparatus, and the papillary dermis. Nearby blood vessels are thrombosed, but there is only mild inflammation in the dermis. In chronic states, some vascular proliferation and ectasia may occur.

PURPURA FULMINANS

Purpura fulminans is a rare clinical manifestation of DIC in which there are large cutaneous ecchymoses and hemorrhagic necrosis of the skin resulting from thrombosis of the cutaneous microvasculature.⁴⁶ It is not known why only certain patients with DIC develop the full picture of purpura fulminans. Hypotension and fever are also present, but visceral manifestations are uncommon. Only a few cases have been reported in adults,^{118–120} the majority arise in infancy and early childhood some days after an infectious illness,¹²¹ usually of streptococcal, meningococcal,^{122,123} pneumococcal,¹²⁴ or viral⁵⁵ etiology. A number of cases associated with varicella infection have been reported in recent years.^{125,126} An association with malaria has been reported.¹²⁷ Rarely, purpura fulminans occurs in the neonatal period associated with severe congenital deficiency of protein C or protein S.^{46,47,55} Protein S is a cofactor for protein C. Acquired deficiencies of these proteins, probably due to the primary infectious process, appear to be responsible for cases in later life, but they are also responsible for some cases of purpura fulminans in childhood.⁵¹ The factor V Leiden mutation has been incriminated in a small number of adult and childhood cases.¹²⁰

The cutaneous lesions can commence as erythematous macules that rapidly enlarge and develop central purpura. The central zone becomes necrotic, and the eventual removal of the resulting eschar leads to an

area of ulceration.⁴⁶ There is a predilection for the lower extremities and the lateral aspect of the buttocks and thighs. Peripheral gangrene may sometimes develop. The use of fresh frozen plasma has considerably improved the prognosis of this disease. Administration of human protein C concentrate has been beneficial in some cases.¹²⁸

Histopathology⁴⁶

Fibrin thrombi fill most of the venules and capillaries in the skin. There is a mild perivascular infiltrate in some areas, but no vasculitis. Extensive hemorrhage is present with the subsequent development of epidermal necrosis. Occasionally, a subepidermal bulla develops.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura is a rare syndrome characterized by the clinical picture of microangiopathic hemolytic anemia, thrombocytopenia, neurological symptoms, renal disease, and fever.¹²⁹⁻¹³¹ Cutaneous hemorrhages in the form of petechiae and ecchymoses are quite common.¹²⁹ Prior to the introduction of plasmapheresis and antiplatelet agents, the disease was almost invariably fatal.

It appears to result from prostacyclin inhibition and impaired fibrinolysis. Although drugs, infectious agents, and obstetric incidents have been implicated in triggering this syndrome, in the majority of individuals there is no apparent causal event or underlying disease process.¹²⁹ Drugs incriminated include the antiplatelet drugs ticlopidine and clopidogrel.¹³²⁻¹³⁴ Coagulation studies fail to show evidence of DIC.

Histopathology

Platelet-rich thrombi admixed with a small amount of fibrin deposit in vessels at the level of the arteriolo-capillary junction.¹²⁹ They may also involve small arteries.¹³¹ There may be slight dilatation of vessels proximal to the thrombi. The material is PAS positive. There is no evidence of any associated vasculitis. Extravasation of red blood cells also occurs. In severe cases, necrosis of the epidermis may ensue.

THROMBOCYTHEMIA

Thrombocythemia is a rare, chronic myeloproliferative disorder characterized by a significant increase in the platelet count. Cutaneous manifestations, which include livedo reticularis, erythromelalgia, and ischemic manifestations, occur in approximately 20% of patients.¹³⁵⁻¹³⁷ Platelet plugging, leading to erythematous plaques, may develop in other myeloproliferative disorders.¹³⁸

Histopathology

If biopsies are taken from areas of erythromelalgia, there is fibromuscular intimal proliferation involving arterioles and small arteries similar to the changes seen in Sneddon's syndrome.¹³⁹⁻¹⁴²

In a case associated with both erythromelalgia and livedo reticularis, biopsy of the latter showed hyalinized, thrombosed deep dermal vessels with perivascular lymphohistiocytic infiltrates.¹⁴³ If ischemic areas are biopsied, there is vascular thrombosis, which may involve vessels of all sizes. Infarction of the dermis and/or epidermis may accompany these thrombosed vessels.

CRYOGLOBULINEMIA

Cryoglobulins are immunoglobulins that reversibly precipitate from the serum or plasma on cooling.^{144,145} There are two distinct types of cryoglobulinemia, monoclonal (type I) and mixed (type II), which reflect the composition of the cryoglobulins involved.¹⁴⁶ In the monoclonal type, intravascular deposits of cryoglobulins can be seen in

biopsy specimens, whereas the mixed variant is a vasculitis. They are considered together for convenience.

Monoclonal cryoglobulinemia

The monoclonal variant, which accounts for approximately 25% of cases of cryoglobulinemia, is associated with the presence of IgG or IgM cryoglobulin or, rarely, of a cryoprecipitable light chain.^{144,147} Monoclonal cryoglobulins, also known as type I cryoglobulins, are usually seen in association with multiple myeloma, Waldenström's macroglobulinemia,¹⁴⁸ and chronic lymphatic leukemia.^{144,149,150} Sometimes, no underlying disease is present (essential cryoglobulinemia). The condition may be asymptomatic or result in purpura, acral cyanosis, or focal ulceration, which is usually limited to the lower extremities.^{151,152} Generalized livedo reticularis is another manifestation.¹⁵³ In a study of 15 patients with leg ulcers associated with cryoglobulinemia, 8 patients had type I cryoglobulins and 7 patients had type II.¹⁵⁴ Plasma exchange combined with immunosuppressive drugs usually cures the ulcers.¹⁵⁴ Thalidomide, rituximab, and bortezomib have also been used.¹⁵⁵

Mixed cryoglobulinemia

In the mixed variant, the cryoglobulins are composed of either a monoclonal immunoglobulin that possesses antibody activity toward, and is attached to, polyclonal IgG (type II) or two or more polyclonal immunoglobulins (type III).¹⁵⁶ Mixed cryoglobulins usually take the form of immune complexes and interreact with complement. They are seen in autoimmune diseases such as rheumatoid arthritis, SLE, and Sjögren's syndrome; in lymphoproliferative diseases;¹⁵⁷ as well as in various chronic infections resulting from the hepatitis and Epstein-Barr viruses.^{156,158} Numerous cases associated with infection with the hepatitis C virus have been reported in recent years.¹⁵⁹⁻¹⁷¹ Vasculitis can also occur in patients with hepatitis C virus who do not have mixed cryoglobulinemia; clinical differences are slight, except for a higher incidence of arthralgias among those who do have mixed cryoglobulinemia.¹⁷² A mixed cryoglobulinemia may be the etiology of some cases of the 'red finger syndrome' seen in patients with HIV or hepatitis infection.¹⁷³ Association with parvovirus B19 infection has been reported on several occasions.¹⁷⁴⁻¹⁷⁶ In other patients, no etiology or pathogenesis is apparent.¹⁷⁷ In approximately 50% of cases, no detectable autoimmune, lymphoproliferative, or active infective disease is present.¹⁷⁸ These cases of essential mixed cryoglobulinemia are characterized by a chronic course with intermittent palpable purpura, polyarthralgia, Raynaud's phenomenon, and occasionally glomerulonephritis.^{158,178} In a recent survey of mixed cryoglobulinemia, 13 of 33 patients had essential mixed cryoglobulinemia; these individuals tended to have more severe disease than those with secondary forms of the disease, and they more often developed renal and peripheral nerve involvement.¹⁷⁹ Other cutaneous manifestations that may be present include ulcers, urticaria, digital necrosis, and, rarely, pustular purpura.¹⁸⁰

A localized cryoglobulinemic vasculitis can be seen in tick bite reactions, particularly when tick mouthparts are retained in the tissue.¹⁸¹

Histopathology¹⁴⁶

Monoclonal cryoglobulinemia

Purpuric lesions will show extravasation of red blood cells into the dermis. Small vessels in the upper dermis may be filled with homogeneous, eosinophilic material that is also PAS positive.^{147,151,182} These intravascular deposits are seen more commonly beneath areas of ulceration.¹⁵¹ Although there is generally no vasculitis, there may be a perivascular infiltrate of predominantly mononuclear cells (Fig. 8.4).¹⁸² Microscopic changes of leukocytoclastic vasculitis have been reported in one case of monoclonal cryoglobulinemia (associated with

Figure 8.4 Monoclonal cryoglobulinemia. Thrombi are evident, but there is also mild permeation of the involved vessels by neutrophils. (H&E)

Waldenström's macroglobulinemia).¹⁸³ Vacuole-like cytoplasmic inclusions were found in peripheral blood neutrophils, monocytes, lymphocytes, and platelets (but not in bone marrow cells) in cryoglobulinemia associated with IgG-κ monoclonal gammopathy; this was of undetermined significance.¹⁸⁴

Mixed cryoglobulinemia

The histological features are those of an acute vasculitis.¹⁷⁰ There may be some variation from case to case in the extent of the infiltrate and the degree of leukocytoclasia, probably reflecting the stage of the lesion.¹⁸⁵ There are usually some extravasated red blood cells; in cases of long standing, hemosiderin may be present. Intravascular hyaline deposits are the exception, but they may be found beneath areas of ulceration.^{156,180} A septal panniculitis is a rare association.¹⁸⁶ Immunoglobulins and complement are often found in vessel walls by immunofluorescence.¹⁸⁵

Electron microscopy

The ultrastructural features depend on the involved immunoglobulins and on their respective quantities. There may be tubular microcrystals, filaments, or cylindrical and annular bodies.¹⁸⁰ In a recently reported case of monoclonal cryoglobulinemia, immunoglobulin crystalloid structures were present within the small cutaneous vessels, admixed with fibrin and red blood cells.¹⁸⁷

Differential diagnosis

Despite the possible clinical resemblance between lesions of perniosis and cryoglobulinemia, these diseases are not associated in adult patients.¹⁸⁸ The microscopic findings are quite different, with perniosis showing perivascular lymphocytic infiltrates with evidence for lymphocytic vasculitis.

CHOLESTEROL AND OTHER TYPES OF EMBOLISM

Embolism to the skin is no longer restricted to cholesterol crystals. It may involve exogenous material introduced during a procedure or consist of detached tumor fragments. Cutaneous involvement occurs in 35% of patients with cholesterol crystal embolization.^{189–192} The incidence was much higher in a study of cholesterol embolism.¹⁹³ The source of the emboli is atheromatous plaques in major blood vessels,

particularly the abdominal aorta. This material may dislodge spontaneously or following vascular procedures or anticoagulant therapy.¹⁹⁴ There is a high mortality. Cutaneous lesions are found particularly on the lower limbs and include livedo reticularis, gangrene, ulceration, cyanosis, purpura, and cutaneous nodules.^{189,195–198} Rare manifestations have included erythematous and hyperpigmented papules and plaques on the trunk,¹⁹⁹ a hemorrhagic panniculitis on the chest,²⁰⁰ and an eschar on the ear.²⁰¹

Histopathology^{189,195,202}

Multiple sections are sometimes required to find the diagnostic acicular clefts indicating the site of cholesterol crystals in arterioles and small arteries in the lower dermis or subcutis.²⁰³ A fibrin thrombus often surrounds the cholesterol material. Foreign body giant cells and a few inflammatory cells may also be present. Rarely, there are numerous eosinophils.¹⁹⁹ Cutaneous infarction and associated inflammatory changes sometimes develop. Cholesterol emboli may be an incidental finding.^{204,205}

Deposits of **atrial myxoma** in peripheral arterioles and small arteries may at first glance be mistaken for cholesterol emboli.²⁰⁶ However, a loose myxoid stroma and lack of cholesterol clefting should allow a confident diagnosis of 'metastatic' atrial myxoma.^{207,208}

Deposits of **catheter tip** can also form cutaneous emboli if fragments break off during a procedure.²⁰⁹ In one such case, purpuric lesions developed on the palm and fingers following percutaneous cardiac catheterization through the brachial artery.²⁰⁹

Arterial embolization may follow the injection of hyaluronic acid used for tissue augmentation,²¹⁰ and follow the use of acrylic cement during vertebroplasty.²¹¹

ANTIPHOSPHOLIPID SYNDROME

The antiphospholipid syndrome is characterized by the presence of autoantibodies directed against phospholipids and associated with repeated episodes of thrombosis, fetal loss, and thrombocytopenia.^{212–221} These antibodies can be detected as a lupus anticoagulant, as anticardiolipin, or as anti-β₂ glycoprotein I-dependent antibodies.²²² A seronegative category of antiphospholipid syndrome is now being recognized.²²² Antibodies can be found in 20–50% of patients with SLE, but only approximately half of these patients have the antiphospholipid syndrome. The syndrome may also occur in association with rheumatoid arthritis, infections, dermatographism, urticaria, certain drugs, and malignant disorders.^{215,223} The term 'primary antiphospholipid syndrome' is used for patients who do not have an associated disease. Revised criteria for the diagnosis of antiphospholipid syndrome have been evaluated with particular application to patients presenting with dermatological symptoms.²²⁴ It has been suggested that anetoderma is a cutaneous marker for the antiphospholipid syndrome.^{225,226}

Patients may be asymptomatic or develop thrombosis with systemic and/or cutaneous disease.²²⁷ Skin lesions include livedo reticularis, Raynaud's phenomenon,²²⁸ thrombophlebitis, cutaneous infarction and gangrene of the digits, ulceration, subungual splinter hemorrhages, and painful skin nodules resembling vasculitis (but without vasculitis on biopsy).^{215,229–232} Antiphospholipid antibodies can be associated with Sneddon's syndrome (see later).²³³ Cutaneous necrosis can sometimes be quite extensive.^{234,235} Gangrene of the digits in a newborn was attributed to maternal antiphospholipid syndrome.²³⁶ There are isolated reports of its association with atrophie blanche, malignant atrophic papulosis (Degos),²¹⁵ hyperhomocysteinemia (OMIM 603174),^{237,238} and factor V Leiden mutation.²³⁹

It is not known why only a minority of patients with the autoantibodies develop thrombotic complications.²⁴⁰ Furthermore, the mechanisms by which the thromboses occur are poorly understood.^{227,241}

Thrombotic events should be treated with anticoagulants, initially heparin, followed by long-term warfarin titrated to an INR of 2–3.²⁴²

Histopathology

In early cutaneous lesions, there is prominent dermal edema and hemorrhage with thrombi in both arteries and veins.²⁴³ Some endothelial cells may have pyknotic nuclei, whereas others are swollen and disrupted. There is usually a mild lymphocytic infiltrate around involved vessels, and sometimes there are plasma cells as well. There is no vasculitis. In livedo reticularis lesions, thrombosis is not generally identified, except in ‘catastrophic’ disease; instead, one may see vascular proliferation or endarteritis obliterans.²⁴⁴ Painful, small ulcers show fibrin deposition in and around dermal vessels and hyalinization of vessel walls.²⁴⁴

In later lesions, there is organization of thrombi and subsequent recanalization. Reactive vascular proliferation develops. Some endothelial cells may be prominent and contain eosinophilic globules similar to those seen in Kaposi’s sarcoma. Hemosiderin pigment is also present in late lesions.²⁴³ Some vessels may show intimal hyperplasia. This may reflect organization of earlier mural thrombi.²⁴⁵ A panniculitis has been described, manifesting as tender nodules on the legs. Microscopic features included a mixed septal and lobular panniculitis, with septal fibrosis, fat necrosis, mucin deposition, and an infiltrate composed of histiocytes, neutrophils, and eosinophils.²⁴⁶

FACTOR V LEIDEN MUTATION

Resistance to activated protein C (APC), leading to a hypercoagulable state, occurs in 2–5% of the U.S. population. It is more frequent in some areas of Europe.¹²⁰ In most patients, this APC resistance is caused by a single point mutation (Leiden mutation) involving a substitution of glutamine for arginine in the gene (*F5*) encoding factor V, situated at 1q23 (OMIM 227400).^{239,247,248} This mutation makes the activated form of factor V relatively resistant to degradation by APC.²⁴⁹ Other mutations causing APC resistance have been described.

The factor V Leiden mutation increases the risk of venous thrombosis up to 10-fold. It is an important cause of venous leg ulcers.^{239,250–253} The condition may enhance other pro-clotting defects or drugs to produce vascular thrombosis.^{254–257} In the presence of the mutation, trauma may produce leg ulcers.²⁵⁸ It has also been found that this mutation is increased in patients who present with leg ulcers caused by leukocytoclastic vasculitis.²⁵⁹ It has been suggested that the gene confers selective evolutionary advantages in those individuals who carry it – a likely explanation for its high prevalence in the community. In previous times, people did not live long enough for its adverse thrombotic effects to become manifest.⁵⁸

SNEDDON’S SYNDROME

Sneddon’s syndrome (OMIM 182410) is a rare neurocutaneous disorder of uncertain etiology, characterized by widespread livedo reticularis and ischemic cerebrovascular manifestations resulting from damage to small and medium-sized arteries.^{139,260–267} It may present with ulcers on the lower legs.²⁶⁸ It most commonly affects young and middle-aged females; it is rare in children.²⁶⁹ It has a chronic progressive course and a mortality rate of approximately 10%.²⁷⁰

Detailed pathological studies by Zelger *et al.* have shown an ‘endothelitis’ in affected vessels, followed by a subendothelial proliferation of smooth muscle cells and fibrosis.²⁶³ Vascular occlusion may occur (see later). Antiendothelial cell antibodies have been demonstrated in 35% of patients with Sneddon’s syndrome, but their significance in the pathogenesis is uncertain.²⁶⁴ Possibly of greater relevance is the finding of similar intimal changes in thrombocythemia,

suggesting that platelet-derived factors may also play a role in the pathogenesis of Sneddon’s syndrome.¹³⁹ Other factors appear to be important because Sneddon’s syndrome can occur in association with the antiphospholipid syndrome (discussed previously) and with SLE.²⁷¹ In one case, dysfibrinogenemia was present.²⁷²

Treatment is often unsatisfactory. Rheological agents (heparin, warfarin, and coumarin) are usually tried first. These may be taken with immunosuppressive agents such as corticosteroids, azathioprine, or cyclophosphamide. Intravenous immunoglobulin has also been used.²⁶⁸ Intravenous recombinant tissue plasminogen activator has been used in one patient with Sneddon’s syndrome and acute ischemic stroke, with subsequent improvement in neurologic status.²⁷³

Histopathology

The sensitivity of skin biopsies in Sneddon’s syndrome has been evaluated. The white areas, rather than the red areas, should be biopsied.²⁷⁰ The sensitivity of one 4-mm biopsy is only 27%, but if three biopsies are taken, it increases to 80%.²⁷⁰ In the skin, small to medium-sized arteries near the dermal–subcutaneous junction are affected in a stage-specific sequence.^{265,266} The initial phase involves attachment of lymphohistiocytic cells to the endothelium with detachment of the endothelium (‘endothelitis’). This is followed by partial or complete occlusion of the lumen by a plug of fibrin admixed with the inflammatory cells. This plug is replaced by proliferating subendothelial cells, which have the markers of smooth muscle cells. A corona of dilated small capillaries usually develops in the adventitia. Fibrosis of the intima or the plug may occur. Shrinkage and atrophy of these vessels then occurs.^{265,266}

CADASIL

CADASIL is the acronym used in preference to cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (OMIM 125310), a vascular disorder associated with migraines, recurrent ischemic strokes, and early onset dementia.^{274,275} There is luminal obliteration of small leptomeningeal and intracerebral arteries but no vascular occlusion in the skin. Clinically apparent skin involvement is usually absent, but one case presented with hemorrhagic macules and patches.²⁷⁶ The defect involves a mutation in the *NOTCH3* gene on chromosome 19q12, which encodes a transmembrane receptor protein.²⁷⁷ A commercial laboratory test for this gene is now available.²⁷⁸

Electron microscopic examination of skin biopsies is diagnostic.^{274,277,279} A granular, electron-dense, osmiophilic material is present in the basement membrane of vascular smooth muscle cells.²⁸⁰ Because the deposits may be patchy in superficial dermal vessels, several sections should be searched to avoid a false-negative result. Light microscopy is usually normal, but one case showed thickened and dilated vessels in the papillary dermis as a consequence of deposits of fibrin, complement, and immunoglobulins that were confirmed by immunofluorescence.²⁷⁶ A few perivascular lymphocytes were also present.

MISCELLANEOUS CONDITIONS CAUSING VASCULAR OCCLUSION

Rare causes of cutaneous microthrombi include the hypereosinophilic syndrome;²⁸¹ paroxysmal nocturnal hemoglobinuria;^{282,283} renal failure with hyperparathyroidism (the vascular calcification–cutaneous necrosis syndrome),^{284–286} protein C and/or protein S deficiency;^{287–289} increased activity of factor VIII coagulant;²⁹⁰ cryofibrinogenemia;^{291,292} dopamine,²⁹³ vasopressin,²⁹⁴ Depo-Provera[®],²⁹⁵ and heparin therapy

(*embolia cutis medicamentosa*);^{235,296–299} the use of intravenous immunoglobulin,³⁰¹ temazepam, or flunitrazepam;³⁰² the treatment of afibrinogenemia;³⁰³ ulcerative colitis;³⁰⁴ and embolic processes, including bacterial endocarditis. The eschar found in some rickettsial infections is a cutaneous infarct with fibrin-platelet thrombi in marginal vessels. A lymphocytic vasculitis is usually present as well.

Cutaneous microthrombi have also been associated with the intravascular injection of large amounts of cocaine.³⁰⁰ Moreover, there have been numerous recent descriptions of a cutaneous vasculopathy associated with levamisole-adulterated cocaine.^{305–308} Levamisole is a white powder used as a ‘cutting agent’ in cocaine. In addition to expanding the volume of the material and thereby increasing profits, levamisole is said to increase the stimulatory and euphoric effects of this drug.³⁰⁸ Skin lesions include tender purpura, with necrosis and eschar formation, involving the ears, and a retiform purpura of the legs and elsewhere.^{305,306} Laboratory abnormalities include leukopenia and a subset of antineutrophil cytoplasmic antibodies (c-ANCA) directed toward human neutrophil elastase (HNE).³⁰⁵ Microscopic examination shows thrombosis and/or vasculitis,³⁰⁹ the small vessel thrombi have a fibrinous appearance and may demonstrate cribriform recanalization.³⁰⁵ Direct immunofluorescence may show changes of vasculitis.³⁰⁶

Vascular occlusion, either partial or complete, may occur in endarteritis obliterans as a result of fibrous thickening of the intima. It may be seen in a range of clinicopathological settings that include peripheral atherosclerosis, Raynaud’s phenomenon, scleroderma, diabetes, hypertension, and healed vasculitis.⁴³ Painful digital infarction may occur in patients with abnormalities in their coagulation factors that may mimic Buerger’s disease, suggesting that this disease needs to be reappraised in light of our new knowledge of these various coagulation disorders.³¹⁰

Obstruction of the vena cava may produce cutaneous symptoms. The superior vena cava syndrome, which occurs when extrinsic compression or intraluminal occlusion impedes blood flow through the vessels, may present as persistent erythematous edema of the face.³¹¹ Obstruction of the inferior vena cava usually results from pelvic tumors, but a case related to factor V Leiden mutation has been reported.²⁴⁹ The patient presented with varicose and thrombosed veins on her abdominal wall.²⁴⁹

Acrocyanosis of uncertain pathogenesis has been reported following the inhalation of butyl nitrite.³¹²

Differential diagnosis

Although the differential diagnosis among possible causes of leukocytoclastic vasculitis or small vessel thrombosis is broad, the combination of these two changes raises three major considerations: levamisole-adulterated cocaine, septic vasculitis, and cryoglobulinemia.

URTICARIAS

Urticaria is a cutaneous reaction pattern characterized clinically by transient, often pruritic, edematous, erythematous papules or wheals that may show central clearing.^{313–315} Angioedema is a related process in which the edema involves the subcutaneous tissues and/or mucous membranes. It may coexist with urticaria.^{316,317} Both urticaria and angioedema may be a manifestation of anaphylaxis, a potentially life-threatening condition that may present with flushing and systemic symptoms.³¹⁸ Both allergic and some physical urticarias may progress to anaphylaxis.³¹⁹

Urticaria is a common affliction, affecting 15% or more of the population on at least one occasion in their lifetime. Most cases are *transient (acute)*, and the etiology is usually detected.³²⁰ Infection was the most frequently documented cause of acute urticaria in one

study.³²¹ The use of antibiotics for viral illnesses is another cause.³²² In one series, food allergies accounted for only 2.7% of acute urticarias in childhood.³²¹ A variant of acute urticaria in infants and young children is the annular form that often results from the use of furazolidone in the treatment of diarrhea.³²³ On the other hand, *chronic urticaria*, which is less common than acute urticaria, is arbitrarily defined as urticaria persisting for longer than 6 weeks. It is idiopathic in approximately 75% of cases.^{314,324,325} It tends to involve middle-aged people, in contrast to acute urticaria, which occurs more commonly in children and young adults. When chronic urticaria does occur in children, the etiological factors are more readily identifiable than in adults.³²⁶ In children, physical factors account for half of the cases of chronic urticaria.³²¹ Chronic urticaria may be aggravated by salicylates, food additives, and the like.^{327–330} This has led to the suggestion that chronic urticaria results from an occult allergy to some everyday substance. An unusual variant of acute urticaria thought to be due to the sexual transfer of ampicillin from one person to his or her hypersensitive partner has been reported.³³¹

Papular urticaria is a clinical variant of urticaria in which the lesions are more persistent than the usual urticarial wheal.³³² It may result from a hypersensitivity reaction to the bites of arthropods such as fleas,³³³ lice, mites, and bed bugs.^{332,334,335} It is more common in young children.³³³ It usually occurs in crops on exposed skin.³²⁵ Erosions are common. Rare clinical variants of urticaria include bullous and purpuric forms,³²⁰ urticaria with anaphylaxis,³²⁰ and recurrent urticaria with fever and eosinophilia.³³⁶

Most of the literature on urticaria refers to the chronic form of the disease because this is often an important clinical problem. The remainder of this discussion refers to chronic urticaria.

CHRONIC URTICARIA

Chronic urticaria is urticaria persisting longer than 6 weeks.³²⁴ There are many variants of chronic urticaria, although they share in common the presence of erythematous papules or wheals. Pruritus is often present; it is worse at night and in the evening.³³⁷ These variants are usually classified etiopathogenetically, as follows:³³⁸

- Physical urticarias
- Cholinergic urticaria
- Angioedema
- Urticarias due to histamine-releasing agents
- IgE-mediated urticarias
- Immune complex-mediated urticarias
- Urticarial dermatitis
- Schnitzler’s syndrome
- Autoinflammatory urticarial syndromes
- Idiopathic urticarias
- Autoimmune chronic urticaria
- Miscellaneous urticarias.

Some overlap exists between these various categories. For example, drugs and foodstuffs may produce chronic urticaria through more than one of the previous mechanisms. Patients with a physical urticaria may also develop an idiopathic urticaria.³³⁹ A good clinical history is essential in the categorization of some cases.³⁴⁰

Physical urticarias

Physical stimuli such as heat, cold, pressure, light, water, and vibration are the most commonly identified causes of chronic urticaria, accounting for approximately 15% of all cases.^{341–344} The incidence was 33.2% in one series³⁴⁵ and 14% in another.³⁴⁶ The wheals are usually of short duration and limited to the area of the physical stimulus.³⁴¹ Accordingly, the physical urticarias tend to occur on exposed areas. Angioedema

may coexist.³⁴⁷ More than one of the physical agents listed previously may induce urticaria in some individuals.³⁴² Some of the physical urticarias can be transferred passively.³⁴⁷⁻³⁴⁹ The physical urticarias undergo spontaneous remission in less than 20% of cases. They have the lowest remission rate of any of the chronic urticarias.³⁴⁵

Cold urticaria, which accounts for 1–3% of all cases of urticaria, is produced at sites of localized cooling of the skin. It is usually acquired, although a rare familial form has been reported.³⁵⁰⁻³⁵⁴ It has now been identified as the familial cold, autoinflammatory syndrome (OMIM 120100) due to a mutation in the *CIAS1* gene on chromosome 1q44 (see p. 247). A variant with localized perifollicular lesions has been reported.³⁵⁵ Cold urticaria may follow a viral illness³⁵⁶ or the use of drugs such as penicillin, an ACE inhibitor,³⁵⁷ or griseofulvin. It has been reported in association with mycosis fungoides.³⁵⁸ A few cases are associated with the presence of cryoproteins.³⁵⁹ In most cases, no underlying cause is found.³⁶⁰ A history of atopy is sometimes present. Antihistamine receptor blockers show the best effect for treating this distressing condition.³⁶¹ Patients should be advised that avoidance of cold exposure is the best prophylaxis.³⁶² Coronary artery bypass grafting has been successfully performed in patients with cold urticaria using isothermic/normothermic blood cardioplegia.^{363,364}

Heat urticaria, by contrast, is exceedingly rare.³⁶⁵⁻³⁶⁷ There are now more than 50 reported cases of this disease.^{368,369} It is more common in females. It presents with an eruption of wheals at sites of exposure to heat. One patient developed wheals and loss of consciousness after taking a hot bath.³⁶⁹ H1 blockers are the treatment of choice.³⁶⁸

Solar urticaria is another rare physical urticaria that results from exposure to sun and light.³⁷⁰⁻³⁷⁹ The prevalence of idiopathic solar urticaria in Tayside, Scotland, was estimated to be 3.1 per 100,000.³⁸⁰ Action spectra are typically broad, with 63% in one series ($n = 87$) reacting to more than one wave band, and the most common provoking wavelengths were the longer UVA and the shorter visible ones.³⁸⁰ The majority of patients are still affected after 10 years. Radiation transmitted through glass affects the majority of patients with this condition.³⁸⁰ One study showed a predominance of UVA sensitization compared to visible light.³⁸¹ An inhibition spectrum may be present, whereby activation occurs following exposure to a certain range of wavelengths, but not if re-irradiation with certain other wavelengths is immediately carried out.^{382,383} Solar urticaria has a faster onset and shorter duration than polymorphic light eruption.³⁸⁴ Progression to or coexisting polymorphic light eruption is not uncommon.^{380,385,386} A rare variant, limited to fixed skin sites, has been reported in three patients.³⁸⁷ A similar fixed urticaria may rarely occur as a manifestation of a drug reaction. Solar urticaria has been induced by tetracycline therapy.³⁸⁸ It has been reported as a manifestation of Churg–Strauss syndrome.³⁸⁹ There is one reported case in which solar urticaria was limited to areas of bruising; evidence indicated that a serum factor was responsible.³⁹⁰

Aquagenic urticaria follows contact with water of any temperature.^{391,392} Sometimes there is an underlying disorder, the expression of which may coincide with the onset of the urticaria. Examples include the myelodysplastic syndrome, the hypereosinophilic syndrome, HIV infection, and an underlying cancer.^{393,394} One case of aquagenic urticaria associated with occult papillary thyroid carcinoma improved following total thyroidectomy.³⁹⁵ A rare familial form (OMIM 191850) has been identified,³⁹⁶ and the condition has been described in monozygotic twins.³⁹⁷ Much more common is *aquagenic pruritus*, in which prickly discomfort occurs in the absence of any cutaneous lesion.³⁹⁸⁻⁴⁰³ It appears to be an entity distinct from aquagenic urticaria and may follow increased degranulation of a normal number of mast cells.⁴⁰⁴

In *pressure urticaria*, deep wheals develop after a delay of several hours following the application of pressure.⁴⁰⁵⁻⁴⁰⁸ It is probably more common than generally realized, being present in some patients who do not report pressure-related wheals.^{409,410} It can affect quality of life.⁴¹¹ Systemic symptoms, which include an influenza-like illness, may

also develop.⁴¹² A bullous form with intraepidermal bullae filled with eosinophils has been reported. Many eosinophils were also in the dermis.⁴¹³ Eosinophil granule major basic protein and neutrophil granule elastase are significantly increased in delayed pressure urticaria, in a similar manner to the IgE-mediated late phase reaction. There is no increase of these products in dermographism.⁴¹⁴ Other abnormalities include elevated interleukin-6 (IL-6), C-reactive protein,⁴¹⁵ and plasma D-dimer concentration, the latter possibly a result of the systemic inflammatory response.⁴¹⁶ It usually responds poorly to treatment, but tranexamic acid produced resolution in one reported case.⁴¹⁷ *Vibratory urticaria* is a related disorder resulting from vibratory stimuli.³⁴²

Dermographism, which is the production of a linear wheal in response to a scratch, is an accentuation of the physiological whealing of the Lewis triple response.⁴¹⁸ It has followed trauma from a coral reef⁴¹⁹ and has been reported in patients with adult-onset Still's disease.⁴²⁰ Minor forms of dermographism are quite common, but only a small percentage of affected persons are symptomatic with pruritus. A delayed form, which is an entity similar to delayed pressure urticaria, also occurs.⁴⁰⁷ *Galvanic urticaria* follows the administration of an electrical current given during iontophoresis.⁴²¹

The physical urticaria that is least well understood is *contact urticaria*.⁴²²⁻⁴²⁷ In this variant, a wheal and flare response is usually elicited 30–60 minutes after skin contact with various chemicals in medicaments, cosmetics, foods, and industrial agents.^{422,428} Contact with cosmetics appears to be responsible for the persistent erythema and edema of the mid-third and upper aspect of the face, called morbus morbihan by French dermatologists.⁴²⁹ It may follow exposure to the common stinging nettle (*Urtica dioica*)⁴³⁰ and a long list of other substances, including latex,^{431,432} flavored toothpaste,⁴³³ insect repellent,⁴³⁴ formaldehyde,⁴³⁵ cornstarch powder,⁴³⁶ apples,⁴³⁷ tofu,⁴³⁸ topical immunotherapy with diphenylcyclopropenone,⁴³⁹ petrol, and kerosene. Contact urticaria may follow the application of *p*-chloro-*m*-cresol, a preservative used in a number of topical preparations.⁴⁴⁰ Distinction from a contact irritant dermatitis may sometimes be difficult.⁴⁴¹ An IgE-mediated form and a non-immunological form have been delineated.^{441,442} Contact urticaria may be superimposed on an 'eczematous dermatitis' of different types.⁴²² A recurrent urticaria has been reported at the previous injection sites of insulin.⁴⁴³ Contact sensitization appears to play an important role in other types of chronic urticaria. In a study of 121 patients with chronic urticaria, 50 (41%) tested positive to contact allergens.⁴⁴⁴ In all patients, avoidance measures led to a complete remission within 1 month.⁴⁴⁴ In an Australian study of occupational contact urticaria, natural rubber latex accounted for the majority of cases. Other common causes were foodstuffs and ammonium persulfate utilized as hairdressing bleach.⁴⁴⁵ Atopy was a significant risk factor.

Cholinergic urticaria

Cholinergic urticaria is produced by exercise, heat, and emotion, with general overheating of the body as the final common pathway.^{343,446-449} Accordingly, it is sometimes included with the physical urticarias, with which it may coexist.^{450,451} Young adults are mainly affected, but the condition is usually mild, not requiring medical attention.^{452,453} *Adrenergic urticaria* is a related condition that is also caused by stress. It is distinguishable from cholinergic urticaria because each papule in adrenergic urticaria is surrounded by a striking white halo of blanched vasoconstricted skin.⁴⁵⁴

We have seen several cases of cholinergic urticaria in medical practitioners, and others, following a game of golf. Marathon runners may also experience a cholinergic urticaria.⁴⁵⁵ Both groups, as well as patients participating in exercise, may experience a vasculitis instead of urticaria. Angioedema and anaphylaxis are other manifestations of exercise.^{456,457}

An attempt has been made to classify cholinergic urticaria into four subtypes: with poral occlusion, with acquired generalized

hypohidrosis, with sweat allergy, and idiopathic.⁴⁵⁸ A subtype of generalized anhidrosis – idiopathic pure sudomotor failure – begins at an early age, shows sudden onset, and is accompanied by generalized pain or cholinergic urticaria and an elevated serum IgE level.⁴⁵⁹ The lesions of cholinergic urticaria are distinctive and consist of 2- to 3-mm wheals surrounded by large erythematous flares.³⁴³ There is a predilection for blush areas. Increased sympathetic activity may result in the release of acetylcholine at nerve endings, causing mast cells to degranulate.⁴⁶⁰

Angioedema

Angioedema refers to abrupt and short-lived swelling of the skin, mucous membranes, or both, including the upper respiratory and intestinal epithelial linings.⁴⁶¹ It shows a predilection for areas where the skin is lax, especially the face and genitalia.⁴⁶² It should be distinguished from lymphedema.⁴⁶³ Angioedema results from an increase in permeability of capillaries and postcapillary venules, resulting from either mast cell degranulation or activation of kinin formation.⁴⁶¹ The former group (mast cell degranulation), which includes those due to NSAIDs and autoimmune mechanisms, is usually accompanied by urticaria,⁴⁶⁴ but the ‘kinin group’ due to angiotensin-converting enzyme (ACE) inhibition of bradykinin degradation is not accompanied by hives (see later).⁴⁶¹ In most cases, the NSAID-induced urticaria/angioedema is pharmacological, involving inhibition of cyclooxygenase (COX), a rate-limiting enzyme in the biosynthesis of prostaglandins.⁴⁶⁵ COX-2 inhibitors do not induce urticaria in these patients.⁴⁶⁵

Angioedema is often seen at the injection site of granulocyte-monocyte colony-stimulating factor (GM-CSF). It may also be associated with the use of ACE inhibitors,^{466,467} the ingestion of certain foods,⁴⁶⁸ and intrauterine infection with parvovirus B19.⁴⁶⁹ Angioedema induced by ACE inhibitors is due to a mutation in the *XPNPEP2* gene, which encodes aminopeptidase P. The gene is on chromosome Xq25 (OMIM 300145).

There is a special form of angioedema (*hereditary angioedema*) that may be associated with swelling of the face and limbs or involve the larynx with potentially life-threatening consequences.⁴⁷⁰ It results from an absolute or functional deficiency of C1 esterase inhibitor.^{471,472} There are three types of hereditary angioedema.⁴⁷³ Type I (OMIM 106100) accounts for 85% of cases. It is caused by mutations in the C1 inhibitor gene *C1NH* (also known as *SERPING 1*) on chromosome 11q11–q13.1.⁴⁷⁴ Serum levels of the gene product C1NA are less than 35% of normal.⁴⁷⁵ In type II, the serum levels are normal or elevated but the protein is nonfunctional. The two types are clinically indistinguishable. The third variant (type III; OMIM 610618) is caused by a mutation in the gene encoding coagulation factor XII (Hageman factor), which is at 5q35.2–q35.3.^{474,476} Misdiagnosis of hereditary angioedema is not uncommon.⁴⁷⁷ It results from unchecked bradykinin formation. *Acquired deficiencies* of C1 esterase inhibitor may be seen in lymphoma and certain autoimmune connective tissue diseases. In one case, there was an associated leukocytoclastic vasculitis.⁴⁷⁸ Treatment with danazol has been effective in many cases of hereditary angioedema.

Urticaria due to histamine-releasing agents

Histamine may be released by mast cells in response to certain drugs, such as opiates, and some foodstuffs, including strawberries, egg white, and lobster.³¹⁴ Familial aggregation of aspirin/NSAID-induced urticaria has been reported. Mutations in the leukotriene C4 synthase (*LTC4S*) gene (OMIM *246530) and the glutathione S-transferase M1 (*GSTM1*) gene (OMIM *138350) have been found in these patients.⁴⁷⁹

IgE-mediated urticarias

Antigen-specific IgE may be responsible for some of the urticarias due to certain foods, drugs,^{480,481} and pollens in addition to the urticaria related to parasitic infestations and stings. More than 300 causes have

been identified. Mast cell degranulation is the final common pathway.³²⁰ Total serum IgE levels are often elevated in patients with chronic urticaria, correlating with severity and duration of the condition.⁴⁸²

Immune complex-mediated urticarias

Immune complexes may be involved in the pathogenesis of the chronic urticaria seen in infectious hepatitis, infectious mononucleosis, SLE, and serum sickness-like illnesses.⁴⁸³ They have also been implicated in the urticarial reactions that are an uncommon manifestation of various internal cancers. In some instances, fever, purpura, and joint pains are also present. The urticaria is usually more persistent, particularly in those cases with an accompanying vasculitis. A serum sickness-like reaction has been seen as a complication of cefaclor, an oral cephalosporin.⁴⁸⁴

Urticarial dermatitis

The term urticarial dermatitis was introduced by Kossard and colleagues for a clinicopathological entity with urticarial and eczematous features that presented with erythematous and pruritic lesions. Some cases resembled a fixed urticaria.⁴⁸⁵ Similar cases have been reported as urticarial papulosis.⁴⁸⁶ Kossard believes that urticarial dermatitis is a subset of dermal hypersensitivity reaction,⁴⁸⁵ a term that has been disputed by many^{487,488} but to which the author is a recent convert (see p. 1134). Mycophenolate mofetil has been used to treat dermal hypersensitivity reaction.⁴⁸⁹

Schnitzler's syndrome

Schnitzler's syndrome combines nonpruriginous chronic urticaria, monoclonal IgM gammopathy, fever, arthralgias, and disabling bone pain.^{490–497} Monoclonal IgG has been present in other cases.^{498,499} An association with cold urticaria has been reported.⁵⁰⁰ The link between these disparate disorders is unknown, but there are some similarities with the autoinflammatory syndromes (see later). Treatment has usually been with systemic corticosteroids, with cyclosporine (ciclosporin),⁴⁹⁸ chlorambucil, or cyclophosphamide used in an attempt to avoid the overuse of corticosteroids. Antihistamines and NSAIDs have also been used. Pefloxacin, given for a concurrent urinary tract infection, produced dramatic and sustained improvement. Its use in other patients with the syndrome produced improvement in most cases.⁵⁰¹ The anti-CD20 monoclonal antibody rituximab has also controlled symptoms.⁵⁰² This treatment failed in another patient who subsequently had a response to anakinra,⁵⁰³ an IL-1 receptor antagonist.⁵⁰⁴ Response to this agent supports the concept that dysregulation of the IL-1 pathway is involved in the pathogenesis of the disease.⁵⁰⁴ Other successful reports have followed.^{505,506}

Autoinflammatory urticarial syndromes

There are several familial urticarial disorders of early onset associated with mutations in the *CIAS1* gene on chromosome 1q44, controlling the formation of cryopyrin.⁵⁰⁷ They are included in the broader group of autoinflammatory diseases, also known as the periodic fever syndromes (see p. 247). The three autoinflammatory diseases in which urticaria is a major feature are familial cold autoinflammatory syndrome (OMIM 120100);⁵⁰⁸ Muckle–Wells syndrome (OMIM 191900), in which progressive deafness is also present, as well as amyloidosis in approximately one-third of affected patients; and neonatal-onset multisystem inflammatory disorder (NOMID, CINCA (OMIM 607115)).^{509,510} Hyperpigmented sclerodermoid lesions have been reported in Muckle–Wells syndrome.⁵¹¹

There are some similarities between these syndromes and cases reported as familial cold urticaria;⁵¹² it was described before the recognition of these cryopyrin-associated syndromes, and they may be the same disorder. The histology is variable, but there may be a heavy interstitial, perivascular, and periadnexal infiltrate of neutrophils that is closer to a neutrophilic dermatosis than a neutrophilic urticaria.⁵⁰⁹

Idiopathic urticaria

Up to 75% of all chronic urticarias fall into the idiopathic category.^{338,513} It accounted for 36% of cases in a series of 220 patients reported in 2001.³⁴⁵ Nearly half of the cases experienced spontaneous remission of their urticaria.³⁴⁵ Up to 50% of patients with idiopathic urticaria have histamine-releasing autoantibodies in their blood that act against the IgE and FcεRIα receptors.^{514,515} Such cases should be recategorized as autoimmune chronic urticaria (see later). Angioedema is present in approximately 40% of cases.⁵¹⁶

Autoimmune chronic urticaria

There is now strong evidence for an autoimmune basis for a group of patients with chronic urticaria, previously classified as idiopathic urticaria.⁵¹⁷ These patients have functional autoantibodies against the α chain of high-affinity IgE receptor (FcεRIα). An additional 10–15% of patients with idiopathic urticaria have antibodies against the IgE molecule.^{518,519} It is difficult to distinguish the autoimmune group from the idiopathic group, although the autologous serum skin test (ASST) is a useful screening test for 'autoreactive' diseases, not autoantibodies.^{518,520} The CD63 expression assay (a modified serum-induced basophil activation test) seems to be a reliable test in the diagnosis of autoimmune chronic urticaria.⁵¹⁸ There is an association with autoimmune thyroid disease in this form of urticaria.⁵²¹

Miscellaneous urticarias

An urticarial reaction is sometimes seen in individuals who are infected with *Candida albicans*,³³⁸ the role of this organism in the causation of urticarias has been overstated in the past. Recently, *Helicobacter pylori* gastritis has been reported in some patients with chronic urticaria,^{522–525} but its etiological significance has since been challenged.^{526–528} Urticaria may be a manifestation of autoimmune progesterone dermatitis (see p. 130), a disorder that is usually manifest some days before the menses.^{529–532} The mechanism is probably not an 'autoimmune' reaction, despite the title.⁵³³ An estrogen-induced urticaria (see p. 131) also occurs.⁵³⁴

Other published causes of urticaria include hepatitis C infection,^{535–537} dental infection,⁵³⁸ IL-3 therapy,⁵³⁹ gelatin in a vaccine,⁵⁴⁰ hepatitis B immunization,⁵⁴¹ rabies vaccine,⁵⁴² ethanol,^{543,544} drugs such as nonsteroidal anti-inflammatory agents,^{545,546} bupropion,^{547,548} povidone in a paracetamol preparation,⁵⁴⁹ methylprednisolone (intra-articular),⁵⁵⁰ bleomycin,⁵⁵¹ polidocanol,⁵⁵² cetirizine,^{553–555} alendronate,⁵⁵⁶ minocycline,^{557,558} nicotine in tobacco smoke,⁵⁵⁹ kava,⁵⁶⁰ ovarian cancer,⁵⁵⁸ multiple piloleiomyomas,⁵⁶¹ lymphoma,⁵⁶² colonic adenocarcinoma,⁵⁶³ carcinoid tumor,⁵⁶⁴ the parasites *Anisakis* sp.,^{565–567} *Blastocystis hominis*,⁵⁶⁸ and *Hymenolepis nana*.⁵⁶⁹ It has also followed contact with hedgehogs,⁵⁷⁰ ants,^{571,572} and caterpillars.⁵⁷³ It has been associated with thyroid autoimmunity,^{574–576} adult Still's disease,^{577,578} and the chronic, infantile, neurological, cutaneous and articular syndrome (CINCA).⁵⁷⁹ Common variable immunodeficiency may present as a chronic urticaria.⁵⁸⁰ Angioedema and urticaria have been associated with the use of isotretinoin,⁵⁸¹ topical imiquimod,⁵⁸² and sodium benzoate.⁵⁸³ Urticaria may develop at a site distal to the application of diphencyprone for resistant viral warts.^{584,585} Acute urticaria has followed the use of 'gomutra' (cow's urine) gargles.⁵⁸⁶

Recall urticaria consists of urticaria in a previously injected site when antigens enter from another source such as orally.⁵⁸⁷

Pathogenesis of urticaria

Urticaria results from vasodilatation and increased vascular permeability associated with the extravasation of protein and fluids into the dermis.⁴⁷¹ Angioedema results when a similar process occurs in the deep dermis and subcutis. Histamine has generally been regarded as the mediator of these changes, although other mediators such as

prostaglandin D₂ and IL-1⁵⁸⁸ are possibly involved in some circumstances.⁴⁰⁶ IL-1 and other cytokines can induce the expression of endothelial adhesion molecules, which is upgraded in urticarial reactions.⁵⁸⁹ Both immunological⁵⁹⁰ (type I and type III) and non-immunological mechanisms can cause mast cells and basophils to degranulate, liberating histamine and other substances.^{471,591} Although immediate (type I), IgE-mediated mast cell release is the classic underlying mechanism of urticarial reactions, there is evidence that delayed-type hypersensitivity reactions are often involved as well. For example, the cytokine IL-4 can upregulate IgE secretion, whereas the opposite occurs with interferon (IFN).³¹⁵ There is also an increase in IL-10-secreting T cells in chronic idiopathic urticaria.⁵⁹² IL-18 is not increased compared to controls.⁵⁹³ The neuropeptide substance P, derived from unmyelinated sensory nerve endings, can also evoke the release of histamine, but not prostaglandin D₂, from cutaneous mast cells.³¹⁵ ACE is one of the major peptidases for the degradation of substance P, but polymorphisms in the ACE gene do not appear to increase the risk of developing chronic urticaria, although they can be a contributing factor to susceptibility of angioedema accompanying chronic urticaria.⁵⁹⁴ Eosinophil degranulation occurs in most urticarias. The number of free eosinophil granules correlates with the duration of the wheal; granules are numerous in wheals of long duration.⁵⁹⁵ The granules may provoke the persistent activation of the mast cells in the wheal.

Other research has been directed at aspects of urticaria not necessarily involving mast cells in the first instance. It has been found that oxidative stress is common to the physical urticarias.⁵⁹⁶ Basophils have become the center of attention once again in chronic urticaria. In addition to the basopenia, intrinsic defects of the anti-IgE cross-linking signaling pathway of basophils have been described. Basophils in these patients have an activated profile, possibly due to an *in vivo* priming by IL-3.⁵¹⁹

Various studies have shown that approximately one-third or more of patients with chronic urticaria have circulating autoantibodies to FcεRIα (the high-affinity IgE receptor), resulting in the release of histamine from mast cells.^{597–599} This subset of patients (autoimmune chronic urticaria) has more severe disease.⁶⁰⁰ An association with HLA class II has been reported.⁶⁰¹ The beneficial effect of cyclosporine and intravenous immunoglobulin on chronic urticaria provides further support for the role of histamine-releasing autoantibodies in its pathogenesis.^{602,603} Extensive laboratory investigations do not contribute substantially to the diagnosis of chronic urticaria or the detection of underlying disorders.⁶⁰⁴

In summary, several different mechanisms have been elucidated that are capable of stimulating the release of histamine from mast cells and/or basophils.

An excellent evidence-based protocol on the management of urticaria has been published by the British Association of Dermatologists.³¹⁹ Practitioners should be aware of dosing, side effects, and potential interactions of the drugs mentioned. A nonsedating H1 antihistamine is the treatment of choice, although not all patients respond. A sedating antihistamine is sometimes used at bedtime. One study demonstrated the effectiveness of the monoclonal antibody, omalizumab, for physical urticarias. This agent selectively binds to free IgE.⁶⁰⁵ Rapid desensitization to autologous sweat has been used in the treatment of cholinergic urticaria.⁶⁰⁶ Other agents used in varying circumstances include corticosteroids, cyclosporine, intravenous immunoglobulin, mycophenolate mofetil, doxepin, scopolamine (in cholinergic urticaria), methotrexate, sulphasalazine, antibiotics, and anticoagulants (for the prevention of NSAID-induced urticaria).⁶⁰⁷

Histopathology of urticarias^{608,609}

The cell type and the intensity of the inflammatory response in urticaria are quite variable.⁴⁰⁶ There is increasing evidence that the age of

the lesion biopsied and the nature of the evoking stimulus may both influence the type and the intensity of the inflammatory response.

Dermal edema, which is recognized by separation of the collagen bundles, is an important feature of urticaria. Mild degrees may be difficult to detect. Urticarial edema differs from the mucinoses by the absence of granular, stringy, basophilic material in the widened interstitium. There is also dilatation of small blood vessels and lymphatics, and swelling of their endothelium is often present (Fig. 8.5). The histopathological changes in urticaria are most marked in the upper dermis, but involvement of the deep dermis may be present, particularly in those with coexisting angioedema.⁶¹⁰

The cellular infiltrate in urticaria is usually mild and perivascular in location. It consists of lymphocytes and, in most cases, a few eosinophils.⁶¹⁰ Occasional interstitial eosinophils and mast cells are also present. Eosinophil granule major basic protein has been identified in the dermis in several types of urticaria.⁶¹¹ Neutrophils are often noted in early lesions, but in most cases they are relatively sparse; there is evidence that they are more prominent in the physical urticarias,⁶¹²⁻⁶¹⁴ particularly delayed pressure urticaria.⁶⁰⁹ A recent study of this form of urticaria, elicited by a pressure-challenge test, emphasized the prominence of eosinophils.⁶¹⁵ Eosinophil extracellular traps have been identified in bullous delayed pressure urticaria using confocal scanning laser microscopy. These structures contain mitochondrial DNA and eosinophil cationic protein and can be found using dual-labeling fluorescent methods. They are believed to constitute a primitive antibacterial defense mechanism.⁶¹⁶ An important diagnostic feature of many early urticarias is the presence of neutrophils and sometimes eosinophils in the lumen of small vessels in the upper dermis.⁶¹³ The presence of neutrophils in other circumstances is discussed later. Although mast cells are often increased in early lesions and even in nonstimulated skin of patients with chronic urticaria,⁶¹⁷ they appear to be decreased in late lesions, apparently due to the failure of histochemical methods to detect degranulated mast cells.^{412,460}

Neutrophils have been described in urticaria in several different circumstances.⁶¹⁸⁻⁶²⁰ As previously noted, a few intravascular and perivascular neutrophils are a common feature in early urticaria.⁶¹⁸ At times, there may be sufficient transmigration of neutrophils through vessel walls to give a superficial resemblance to 'vasculitis', but there is no fibrinoid change, hemorrhage, or leukocytoclasia. A more diffuse dermal neutrophilia has also been described in nearly 10% of urticarias.^{619,621} The term '*neutrophilic urticaria*' is used in these circumstances. In these cases, neutrophils are scattered among the collagen bundles, usually in the upper dermis but sometimes throughout its thickness. The infiltrate is usually mild in intensity.⁶¹⁹ Rare nuclear 'dusting' may also be present. Interstitial eosinophils and perivascular eosinophils and lymphocytes are usually noted as well.⁶¹⁹ Neutrophils are also present in the leukocytoclastic vasculitis that sometimes accompanies chronic urticaria. The term '*urticarial vasculitis*' has been applied to cases of this type in which the clinical picture is that of an urticaria and the histopathology is a vasculitis.⁶²²⁻⁶²⁶ In urticarial vasculitis (also see p. 238) the urticarial lesions are usually of longer duration than in the 'usual' chronic urticaria and may be accompanied by systemic symptoms.⁶²⁷⁻⁶³⁰ The incidence of vasculitis in chronic urticaria varies with the strictness of the criteria used for defining vasculitis.^{631,632} There appears to be a continuum of changes, with a few intravascular and perivascular neutrophils at one end of the spectrum and an established leukocytoclastic vasculitis at the other. In a large series of patients with urticaria subjected to biopsy, 57% were found to have '*neutrophilic urticaria*'. This high percentage was attributed to the tendency to biopsy lesions of new onset. There was no difference in prevalence of rheumatic disease among those with neutrophilic compared to conventional urticaria.⁶³³

Zembowicz and colleagues examined 16 skin biopsies from patients with aspirin-induced chronic idiopathic urticaria. A classic urticarial

Figure 8.5 (A) Urticaria. (B) There is mild dermal edema and a perivascular infiltrate of lymphocytes, mast cells, and eosinophils. Occasional interstitial eosinophils are also present. (C) Intraluminal neutrophils and eosinophils are usually a feature. (H&E)

pattern occurred in the majority of cases (12 of 16). Two biopsies showed an interstitial fibrohistiocytic (granuloma annulare-like) pattern, one showed a sparse perivascular lymphocytic infiltrate, and the other showed a paucicellular dermal mucinosis.⁶³⁴

Other histopathological features have been described in several of the specific types of urticaria. In *dermographism*, perivascular mononuclear cells are increased, even prior to the initiation of a wheal.⁶³⁵ In *contact urticaria*, subcorneal vesiculation and spongiosis have been reported, but this may simply reflect a concomitant allergic or irritant contact dermatitis.⁴²² In *papular urticaria*, the inflammatory cell infiltrate is usually heavier than in other chronic urticarias and consists of a superficial and deep infiltrate of lymphocytes and eosinophils in a perivascular location.^{332,636} The infiltrate is often wedge shaped.⁶³⁷ Interstitial eosinophils may also be present, and in lesions of less than 24 hours' duration there are also some neutrophils.³³² There is variable subepidermal edema. In *angioedema*, the edema and vascular dilatation involve the deep dermis and/or subcutis, although in the hereditary form there is usually no infiltrate of inflammatory cells.³⁴⁷ It is also quite mild in other forms of the disease. In Schnitzler's syndrome, there are often neutrophils in the dermal infiltrate in a perivascular location mimicking a neutrophilic urticaria. Monoclonal IgM and its autoantibody deposit in the epidermis and at the dermoepidermal junction in the region of the anchoring fibrils.⁶³⁸ One case of cholinergic urticaria associated with hypohidrosis showed partial occlusion of the intraepidermal portion of an eccrine sweat duct by keratinous material, with proximal ductal dilatation and periductal lymphocytic infiltration.⁶³⁹

Electron microscopy

There are platelets and other cells in the lumen of mildly dilated vessels in the upper dermis. Lymphocytes and dendritic cells are close to the vessels. Mast cells may be normal or degranulated.⁶⁴⁰ Using immunoelectron microscopy, tryptase and factor XIIIa have been found in the superficial nerves of patients with drug-induced acute urticaria.⁶⁴¹

Differential diagnosis

When urticarial lesions show perivascular lymphocytic infiltrates, the differential diagnosis can be quite broad and includes polymorphic light eruption, drug-induced exanthem, arthropod reaction, viral exanthem, and id reaction. Although the presence of eosinophils often narrows the focus somewhat to drug or arthropod reaction, clearly eosinophils appear in urticaria due to a variety of factors, including (as noted previously) delayed pressure, and they may be entirely absent in reactions to arthropods or drugs. The finding of diffuse neutrophils with mild perivascular inflammation also raises the possibility of cellulitis or erysipelas; bacteria are typically difficult to identify in tissue sections of those lesions. Neutrophilic urticarias usually lack the other features commonly associated with true vasculitis: endothelial swelling, leukocytoclasia, extravasated erythrocytes, and fibrin deposition. If those features are found in varying combinations, one should suspect urticarial vasculitis. Direct immunofluorescence may then be helpful in that vasculitic lesions show immunoglobulin and complement deposition in vessel walls. A recently described group of disorders termed *neutrophilic urticarial dermatosis* can also display leukocytoclasia; disorders showing these changes include SLE, Still's disease (juvenile rheumatoid arthritis), and Schnitzler's syndrome.⁶⁴² Spongiotic changes should ordinarily argue *against* a diagnosis of urticaria, unless another process can be invoked (e.g., superimposed allergic contact dermatitis or secondary eczematization of an urticarial lesion). In addition, both papular urticaria and urticarial dermatitis may show spongiosis. A variety of other dermatoses may well have an urticaria-like dermal component and yet not represent a primary form of urticaria. A variant of follicular mucinosis has been described that has clinical resemblances to urticaria but characteristic features of follicular mucinosis on biopsy.⁶⁴³

ACUTE VASCULITIS

The term 'vasculitis' refers to a heterogeneous group of disorders in which there is inflammation and damage of blood vessel walls.⁶⁴⁴⁻⁶⁴⁶ It may be limited to the skin or some other organ or be a multisystem disorder with protean manifestations. Numerous classifications of vasculitis have been proposed, but there is still no universally acceptable one.^{644,647-652} Even the Chapel Hill Consensus Conference has failed to come up with a problem-free classification.⁶⁵³ Several reviews of cutaneous vasculitis have been published.⁶⁵⁴⁻⁶⁵⁸

Vasculitis can be classified on an etiological basis, although in approximately 50% of cases there is no discernible cause.⁶⁵⁹ Furthermore, a single etiological agent can result in several clinical expressions of vasculitis. A modified etiological classification, based in part upon pathogenesis but taking into account unique clinical and microscopic features, is shown in [Table 8.1](#). The major shortcoming of this type of classification is that it ignores the close interrelationship of the various components of the immune system, more than one of which is likely to be involved in some of the conditions. Another approach to the classification of the vasculitides has been on the basis of the size and type of blood vessel involved because this correlates to some extent with the cutaneous manifestations. For example, small or medium-sized arteries are involved in polyarteritis nodosa, Kawasaki disease, and nodular vasculitis, whereas large arteries are involved in giant cell (temporal) arteritis and Takayasu arteritis and large veins are involved in thrombophlebitis. Both small and large vessels are involved in rheumatoid arthritis and certain 'collagen diseases'. However, most cases of cutaneous vasculitis involve small vessels, particularly venules. The classification to be adopted here is based on the nature of the inflammatory response, with three major categories: acute (neutrophilic) vasculitis, chronic lymphocytic vasculitis, and vasculitis with granulomatosis ([Fig. 8.6](#)). A fourth category, the neutrophilic dermatoses, is included, although most of the diseases in this group have been regarded at various times as instances of acute (neutrophilic) vasculitis. There is an infiltration of neutrophils in the dermis, but there is usually no fibrin extravasation into the vessel wall, a cardinal feature of acute vasculitis.⁶⁶⁰

The following classification has some shortcomings because vasculitis is a dynamic process, with the evolution of some acute lesions into a chronic stage.^{661,662} Furthermore, lesions are sometimes seen in which there are features of both acute and chronic vasculitis. Whether this represents a stage in the evolution of the disease or a change *de novo* is debatable. Each category of vasculitis can be further subdivided into a number of clinicopathological entities.⁶⁶³ In the case of acute vasculitis, they are as follows:

- Leukocytoclastic (hypersensitivity) vasculitis
- Henoch-Schönlein purpura
- Eosinophilic vasculitis
- Rheumatoid vasculitis
- Urticarial vasculitis
- Mixed cryoglobulinemia
- Hypergammaglobulinemic purpura
- Hyperimmunoglobulinemia D syndrome
- Septic vasculitis
- Erythema elevatum diutinum
- Granuloma faciale
- Localized chronic fibrosing vasculitis
- Microscopic polyangiitis (polyarteritis)
- Polyarteritis nodosa
- Kawasaki syndrome
- Superficial thrombophlebitis

Table 8.1 Classification of vasculitis, based on clinical-pathological features and pathogenesis, where known	
Type of Vasculitis	Causes/Comments
Leukocytoclastic vasculitis	Generally neutrophilic; immune complex-mediated
Henoch-Schonlein purpura	
Drug	
Infectious diseases	
Connective tissue diseases	
Malignancy	
Acute hemorrhagic edema	Infants; follows infections or vaccination; does not show IgA deposition
Microscopic polyangiitis	p-ANCA
Purpura hyperglobulinemica (Waldenström)	Associations with Sjögren's syndrome, lupus erythematosus; antibodies to Ro/SSA
Urticarial vasculitis	Causes: drug, connective tissue disease, viral
Leukocytoclastic vasculitis with thrombosis	
Septic vasculitis (gonococcemia, meningococcemia)	
Cryoglobulinemia	
Use of levamisole-adulterated cocaine	
Chronic forms of leukocytoclastic vasculitis	
Granuloma faciale	
Erythema elevatum diutinum	
Large vessel vasculitis	
Buerger's disease (thromboangiitis obliterans)	involves small and medium arteries and veins
Nodular vasculitis	Involves subcutaneous arteries and veins
Polyarteritis nodosa	cutaneous and systemic
Superficial thrombophlebitis	
Mondor's disease	
Eosinophilic vasculitis	With hypereosinophilic syndrome or connective tissue disease
Lymphocytic vasculitis	
Connective tissue diseases, e.g. lupus erythematosus	
Pityriasis lichenoides	
Pigmented purpuric dermatosis	
Perniosis	
Infectious exanthems	e.g. Rocky Mountain Spotted Fever
Granulomatous vasculitis	
Wegener's granulomatosis	c-ANCA
Churg-Strauss syndrome (allergic granulomatosis)	p-ANCA; occasionally c-ANCA
Giant cell (temporal) arteritis	

- Sclerosing lymphangitis of the penis
- Miscellaneous associations.

LEUKOCYTOCLASTIC (HYPERSENSITIVITY) VASCULITIS

The term 'leukocytoclastic vasculitis' has been chosen for this group of vasculitides in place of the equally unsatisfactory term 'hypersensitivity vasculitis'. Common usage has influenced the decision to make this change. To be cynical, if dermatomyositis can be diagnosed in the

Figure 8.6 (A) Acute vasculitis. (B) There is a neutrophilic infiltrate in the walls of small vessels and in their vicinity. (H&E)

absence of myositis, then perhaps leukocytoclastic vasculitis can be diagnosed in the absence of leukocytoclasia, this being the situation in at least 20% of biopsies of otherwise typical cases. Other diagnoses that have been applied to this condition include allergic vasculitis,⁶⁶⁴ hypersensitivity angiitis,⁶⁶⁵ and necrotizing vasculitis.⁶⁶⁶ 'Necrotizing' is a particularly inappropriate group designation. Like leukocytoclasia, necrosis is not invariably present and is usually applied indiscriminately to cases with minimal fibrin extravasation.

Clinical manifestations

Leukocytoclastic vasculitis usually presents with erythematous macules or palpable purpura, with a predilection for dependent parts, particularly the lower parts of the legs.^{667,668} Other lesions that may be present include hemorrhagic vesicles and bullae,⁶⁶⁹ nodules,⁶⁷⁰ crusted ulcers,^{671,672} and, less commonly, livedo reticularis, pustules,⁶⁷³ or annular lesions.⁶⁷⁴⁻⁶⁸⁰ Segmental leukocytoclastic vasculitis has accompanied herpes zoster.⁶⁸¹ Nodular angiomatoid lesions have been described in a patient with IgA-λ myeloma.⁶⁸² An erythema gyratum repens-like eruption occurred in one patient.⁶⁸³ Cases with urticarial lesions are classified separately as urticarial vasculitis (see later). Individual lesions vary from 1 mm to several centimeters in diameter. Large lesions are sometimes painful.⁶⁶³ There may be a single crop of lesions that subside spontaneously after a few weeks or crops of lesions at different stages of evolution that may recur intermittently.⁶⁸⁴ Unilateral⁶⁸⁵ and localized lesions⁶⁸⁶ are rare. Koebnerization is also surprisingly uncommon.⁶⁸⁷

Interestingly, a ‘reverse’ Koebner phenomenon has also been described: disappearance of vasculitic lesions where a pressure bandage had been applied to a skin biopsy site.⁶⁸⁸

Extracutaneous manifestations occur in approximately 20% of affected individuals and include arthralgia, myositis, low-grade fever, and malaise.^{667,689} In a retrospective series of 93 adult patients reported in 2006, extracutaneous involvement was found in 39.8% of patients.⁶⁹⁰ Less commonly, there are renal, gastrointestinal, pulmonary, or neurological manifestations.^{664,667} Bilateral acute angle closure glaucoma was the presenting feature of a case of systemic leukocytoclastic vasculitis.⁶⁹¹ The severity of the histopathological changes is not predictive of extracutaneous involvement.⁶⁹² Many of these cases with systemic manifestations would now be classified as microscopic polyangiitis (polyarteritis) (see p. 242), although renal involvement is still associated with cutaneous small vessel vasculitis.⁶⁹³ There is a low mortality in leukocytoclastic vasculitis; death, when due to the vasculitis, is related to involvement of systemic vessels. In one study of 160 patients with leukocytoclastic vasculitis, the mortality rate was 1.9%.⁶⁸⁹

Etiology

There are several different etiological groups, although in approximately 40% of cases there is no apparent cause. The recognized groups include infections, drugs and chemicals, cancers, and systemic diseases.^{663,667,694} In a retrospective study of 93 adult patients (referred to previously), no obvious cause was found in 44.1%. Drugs and infections were the most common cause.⁶⁹⁰ Miscellaneous causes include certain arthropod bites,¹⁸¹ severe atherosclerosis,⁶⁹⁵ gallbladder vasculitis,⁶⁹⁶ prolonged exercise,⁶⁹⁷ some coral ulcers,⁶⁹⁸ and coronary artery bypass surgery.⁶⁹⁹ Exercise-induced vasculitis can occur in marathon runners,⁴⁵⁵ in females after long walks,⁷⁰⁰ and in golfers.^{701,702} Sometimes only an urticaria is present.

Streptococcal infection of the upper respiratory tract is the most commonly implicated infection.^{663,703} A streptococcal bullous erysipelas has also been associated with a vasculitis.⁷⁰⁴ Other infections include influenza, *Mycobacterium tuberculosis*,^{705,706} *M. haemophilum*, hepatitis B,⁷⁰⁷ herpes simplex,⁷⁰⁸ herpes zoster/varicella,⁷⁰⁸ human herpesvirus 6 (HHV-6),⁷⁰⁹ cytomegalovirus,^{710,711} parvovirus infection,⁶⁴⁷ HIV infection,^{712,713} and malaria.⁶⁶³ It has followed influenza immunization⁷¹⁴ and envenomation of the brown recluse spider (*Loxosceles reclusa*).⁷¹⁵

Drug causes of leukocytoclastic vasculitis include penicillin,⁶⁵⁹ ampicillin,⁷¹⁶ erythromycin,⁷¹⁷ clindamycin,⁷¹⁸ vancomycin,⁶⁹⁰ rifampicin,⁶⁹⁰ the cephalosporins,⁶⁶⁷ sulfonamides,⁷¹⁶ griseofulvin,⁷¹⁶ furosemide (frusemide),⁷¹⁹ levamisole,^{720,721} thiouracil,⁷²² propylthiouracil,⁷²³⁻⁷²⁷ allopurinol,⁷¹⁶ aspirin,⁶⁶⁷ amiodarone,⁷²⁸ phenylbutazone,⁷¹⁶ cimetidine,⁶⁶⁵ G-CSF,⁷²⁹ procainamide,⁶⁶⁵ potassium iodide,⁷¹⁶ gold,⁷³⁰ phenothiazines,⁷³¹ thiazides,⁶⁶⁷ quinidine,⁷¹⁶ mefloquine,^{732,733} disulfiram,⁷³⁰ phenytoin (diphenylhydantoin),⁷¹⁶ atenolol, oxprenolol,⁷³⁴ practolol, alprenolol, propranolol, carvedilol,⁷³⁴ gefitinib,⁷³⁵ celecoxib,⁷³⁶ rofecoxib,⁷³⁶ borteomib,⁷³⁷ rituximab,⁷³⁸ etanercept,^{739,740} infliximab,⁷³⁹ adalimumab,⁷⁴¹ sorafenib,⁷⁴² chlorzoxazone,⁷⁴³ the selective serotonin reuptake inhibitors (sertraline, fluoxetine, paroxetine, and escitalopram),⁷⁴⁴ indinavir,⁷⁴⁵ haloperidol,⁷⁴⁶ sotalol,⁷⁴⁷ tamoxifen,⁶⁸⁶ etoposide,⁷⁴⁸ cytarabine (cytosine arabinoside),⁷⁴⁹ naproxen,⁷⁵⁰ sibutramine,⁷⁵¹ sunitinib,⁷⁵² famcyclovir,⁷⁵³ metformin,⁷⁵⁴ warfarin,⁷⁵⁵ valproic acid,⁷⁵⁶ dronedarone,⁷⁵⁷ erlotinib,⁷⁵⁸ letrozole,⁷⁵⁹ indomethacin,⁷⁶⁰ orlistat,⁶⁶⁹ methimazole,⁷⁶¹ and insulin.⁷⁶² Some of the propylthiouracil vasculitides are ANCA positive.⁷²⁷ Injection-site vasculitis has been reported following the use of IFN- α .⁷⁶³ Chemicals used in industry, drug and food additives,^{764,765} hypsensitizing antigens, nicotine patches,⁷⁶⁶ protein A column pheresis,⁷⁶⁷ pigment used in tattoos,⁷⁶⁸ and intravenous drug abuse can be included in this etiological category.⁷³¹ The herbal supplement black cohosh used for menopausal symptoms can produce a vasculitis.⁷⁶⁹ Chronic cannabis use can produce an arteritis

Table 8.2 Drugs causing vasculitis	
Adalimumab	Interferon- α (injection site)
Allopurinol	Intravenous drug abuse
Alprenolol	Letrozole
Amiodarone	Levamisole
Ampicillin	Mefloquine
Aspirin	Metformin
Atenolol	Methimazole
Black cohosh	Naproxen
Bortezomib	Nicotine patch
Cannabis	Orlistat
Carvedilol	Oxprenolol
Celecoxib	Paroxetine
Cephalosporins	Penicillin
Chlorzoxazone	Phenothiazines
Cimetidine	Phenylbutazone
Clindamycin	Phenytoin
Cytarabine	Potassium iodide
Disulfiram	Practolol
Dronedarone	Procainamide
Erlotinib	Propranolol
Erythromycin	Propylthiouracil
Escitalopram	Quinidine
Etanercept	Rifampicin
Etoposide	Rofecoxib
Famciclovir	Sertraline
Fluoxetine	Sibutramine
Furosemide (frusemide)	Sorafenib
G-CSF	Sotalol
Gefitinib	Sulfonamides
Gold	Sunitinib
Griseofulvin	Tamoxifen
Haloperidol	Tattoo pigments
Indinavir	Thiazides
Indomethacin	Thiouracil
Infliximab	Vancomycin
Insulin	Warfarin

with severe vascular occlusion leading in some cases to amputation of digits.^{770,771} In one reported case, revascularization occurred with aspirin therapy and weaning from cannabis.⁷⁷² The drugs that cause vasculitis are listed in Table 8.2.

The cancers associated with leukocytoclastic vasculitis include lymphomas (e.g., angioimmunoblastic T-cell lymphoma),⁷⁷³⁻⁷⁷⁵ diffuse large B-cell lymphoma,⁷⁷⁶ myelodysplastic syndrome,⁷⁷⁷ mycosis fungoides,⁷⁷⁸ hairy cell leukemia,⁷⁷⁹ chronic lymphocytic leukemia,⁷⁸⁰ multiple myeloma,^{781,782} and visceral tumors⁷⁸³ such as gastric⁷⁸⁴ and colonic⁷⁸⁵ adenocarcinoma, pleural mesothelioma,⁷⁸⁶ squamous cell carcinoma of the lung,⁷⁸⁷ and hypernephroma.⁷⁸⁸

The systemic diseases include SLE, dermatomyositis,⁷⁸⁹ generalized morphea,⁷⁹⁰ mixed connective tissue disease,⁶⁹⁰ Behçet's disease,⁷⁹¹ celiac disease,⁷⁷³ inflammatory bowel disease,⁷⁹² cystic fibrosis,⁷⁹³ Sjögren's disease,^{794,795} subcorneal pustular dermatosis,⁷⁹⁶ pyoderma

gangrenosum,⁷⁹⁷ sarcoidosis,⁶⁷⁴ the Wiskott–Aldrich syndrome,⁷⁹³ and α_1 -antitrypsin deficiency.⁶⁴⁸

Pathogenesis

The pathogenesis of leukocytoclastic vasculitis involves the deposition of immune complexes in vessel walls with activation of the complement system, particularly the terminal components.⁷⁹⁸ This contrasts with microscopic polyangiitis in which immune complexes are often absent. Chemotaxis of neutrophils and injury to vessel walls with exudation of serum, erythrocytes, and fibrin result. Cell adhesion molecules play a critical role in the interaction between the vascular endothelium and leukocytes.⁷⁹⁹ These adhesion molecules are likely to be involved in the recruitment of the neutrophils.⁸⁰⁰ Mast cells may also play a role.⁸⁰¹ The size of the immune complexes, which depends on the valence of the respective antigen and antibody and their relative concentrations (which is in part determined by the number of binding sites on the antigen), determines the likelihood of their deposition.⁶⁶³ The complexes most likely to precipitate are those with antigens bearing two to four binding sites and in a concentration approximately equivalent with antibody.⁶⁶³ These are the largest immune complexes that ordinarily remain soluble.⁶⁶³

Various antibodies have been detected in patients with acute vasculitis, including ANCA and IgA class anticardiolipin antibodies.^{802,803} ANCA-positive vasculitis is known to be associated with the anti-thyroid drug propylthiouracil; both myeloperoxidase ANCA and proteinase-3 ANCA have been reported.^{804,805} In one study, cryoglobulins were found in 25% of cases.⁶⁸⁹

Lymphokines also play an important role in the evolution of the vascular lesions. Interleukins (IL-1, IL-6, and IL-8) are increased in the circulation, as is tumor necrosis factor (TNF). Both TNF and IL-1 may stimulate the endothelium to activate the intrinsic and extrinsic coagulation pathways and reduce its fibrinolytic activity. This may be the explanation for the thrombosis that occurs in vasculitis.⁷⁹⁹

The formation of platelet aggregates appears to play a thus-far unrecognized role in cutaneous small vessel vasculitis.⁸⁰⁶ In all cases of vasculitis, platelet clumps are associated with diffuse immunostaining of the perivascular stroma with the initiator of platelet aggregation, anti-von Willebrand's factor.⁸⁰⁶

Hemodynamic factors such as turbulence and increased venous pressure, as well as the reduced fibrinolytic activity that occurs in the legs, may explain why localization of lesions to this site is common.⁸⁰⁷ Rarely, lesions may develop in areas of previously traumatized skin – the Koebner phenomenon.⁸⁰⁸ The size and configuration of the complexes may also determine the class of vessel affected. The size of the affected vessels correlates with the clinical features. For example, involvement of small dermal vessels results in erythema or palpable purpura, whereas lesions in larger arteries may lead to nodules, ulcers, or livedo reticularis.⁷⁹³ Deep venous involvement results in nodules without ulceration.⁷⁹³

Drug and infection-related vasculitis usually respond to the withdrawal of the drug and the treatment of the infection, respectively. Systemic corticosteroids can be used in severe drug-related cases to hasten the resolution of the disease. In more chronic cases, as seen with some of the tumor-associated and idiopathic vasculitides, other therapy is used, such as dapsone, methotrexate, mycophenolate mofetil, azathioprine, cyclosporine, cyclophosphamide, and intravenous immunoglobulin.^{809,810} Rituximab has been used for small vessel vasculitis, particularly the type II mixed cryoglobulinemic vasculitis.⁸⁰⁹ Hyperbaric oxygen therapy has been used as a successful adjuvant in vasculitides with nonhealing skin ulcers.⁸¹¹

Histopathology⁸¹²

Acute vasculitis is a dynamic process. Accordingly, not all the features described here will necessarily be present at a particular stage in the

Figure 8.7 (A) Leukocytoclastic vasculitis. (B) There is a heavy infiltrate of neutrophils with leukocytoclasia and marked fibrin extravasation. (H&E)

evolution of the disease.⁶⁶³ It is best to biopsy a lesion of 18–24 hours' duration because this will show the most diagnostic features.⁶⁶⁵ The changes to be described usually involve the small venules (postcapillary venules) in the dermis, although in severe cases arterioles may also be affected. Some of the cases involving arterioles would now be classified as microscopic polyangiitis (see p. 242). There is infiltration of vessel walls with neutrophils that also extend into the perivascular zone and beyond. These neutrophils undergo degeneration (leukocytoclasia) with the formation of nuclear dust (Fig. 8.7). Nuclear dust is not synonymous with this condition. LeBoit has reviewed the other circumstances in which it can be found.⁸¹³ The vessel walls are thickened by the exudate of inflammatory cells and edema fluid. There is also exudation of fibrin ('fibrinoid necrosis') that often extends into the adjacent perivascular connective tissue. Endothelial cells are usually swollen and some are degenerate. Thrombosis of vessels is sometimes present. The dermis shows variable edema and extravasation of red blood cells.

In some lesions, particularly those of longer duration, eosinophils and lymphocytes are also present, particularly in a perivascular location. Macrophages, which are scattered in the interstitium even in the early stages, show a time-dependent increase.⁸¹⁴ In vasculitis due to drugs, a mixed inflammatory cell infiltrate of eosinophils, lymphocytes, and occasional neutrophils is commonly seen.⁷¹⁶ The mean eosinophil count per high power field was 5.20 in a series of drug-induced cases

Figure 8.8 Subsiding vasculitis. It is characterized by a perivascular infiltrate of lymphocytes, a hypercellular ('busy') dermis, and some interstitial mucin. (H&E)

and 1.05 in non-drug-induced cases.⁸¹⁵ The vasculitis induced by tamoxifen (discussed previously) was unusual in being localized to the mastectomy scar and right thorax.⁶⁸⁶

In resolving lesions, there is usually only a mild perivascular infiltrate of lymphocytes and some eosinophils. A rare plasma cell may also be present. Perivascular hemophagocytosis is another late feature.⁸¹⁶ A striking feature of late resolving lesions is hypercellularity of the dermis with an increased number of interstitial fibroblasts and histiocytes, giving the appearance of a 'busy dermis' (Fig. 8.8). There is sometimes a mild increase in acid mucopolysaccharides imparting a vague 'necrobiotic' appearance. These findings on the evolutionary changes in vasculitis are based on a study by the author of five cases of leukocytoclastic vasculitis, biopsied several times over the course of a 2-week period. It was never published.

Uncommonly, the subepidermal edema is so pronounced that vesiculobullous lesions result. Cutaneous infarction, usually involving only the epidermis and upper third of the dermis, may follow thrombosis of affected vessels. Presumptive ischemic changes are not uncommon in sweat glands, even in the absence of infarction.⁸¹⁷ They include apoptosis, necrosis, and basal cell hyperplasia. Rare changes reported in leukocytoclastic vasculitis include epidermal lichenoid changes,⁸¹⁸ subepidermal microabscess formation resembling dermatitis herpetiformis,⁸¹⁹ and intraepidermal vesiculation with acantholytic cells containing vacuolated nuclei.⁸²⁰ Cytomegalovirus-associated vasculitis can sometimes occur without inclusion body changes.⁷¹¹

Although previous studies suggested that direct immunofluorescence is not particularly useful unless performed on lesions less than 6 hours old,^{644,659} recent studies have found fibrinogen, C3, and IgM in early lesions; albumin, fibrinogen, and IgG in fully developed lesions; and mainly fibrinogen, with some C3, in late lesions.⁸²¹ Lesional skin is more often positive than nonlesional skin.⁸²² Another study found vascular deposits of immunoglobulin in 81% of cases. The presence of immunoglobulin was seen more often in patients who had at least one extracutaneous manifestation.⁸²³ The presence of IgA was a strong predictor of renal disease.⁸²³ E-selectin (ELAM-1) is present early in the course of vasculitis but decreases as the lesion evolves.⁸¹⁴

Differential diagnosis

The main differential diagnostic problem is the recognition of leukocytoclastic vasculitis when changes are subtle, obscured by dense inflammation, or mimicked (to an extent) by neutrophilic perivascular infiltrates. Diagnosis therefore requires careful inspection of vessel changes, facilitated at times by multiple levels and direct immun-

fluorescence study. One must also be aware of the phenomenon of 'secondary vasculitis' as seen, for example, at the base of ulcers or in heavy neutrophilic dermal infiltrates. In such circumstances, it is worthwhile to evaluate those vessels that are not in the immediate vicinity of an ulcer and to examine for evidence of true vessel injury. Some examples of *neutrophilic urticaria*, a potential clinical mimic of urticarial vasculitis, can create considerable diagnostic difficulty. This form of urticaria consists of long-standing lesions that are accompanied by pain rather than pruritus. Included are a number of the 'physical urticarias' – cholinergic, cold, and delayed pressure urticarias. Neutrophils aggregate around dermal vessels, but leukocytoclasia is not observed, nor is there evidence for endothelial injury or fibrin deposition.

HENOC-SCHÖNLEIN PURPURA

The Henoch-Schönlein variant of leukocytoclastic vasculitis, which represents approximately 10% of all cases of cutaneous vasculitis, is characterized by a purpuric rash, usually on the lower parts of the legs, which is often accompanied by one or more of the following: arthritis, abdominal pain, hematuria, and, rarely, cardiac or neurological manifestations.⁸²⁴⁻⁸²⁶ Intussusception is an uncommon disease complication that has been reported with increasing frequency in recent years.⁸²⁷⁻⁸²⁹ Pancreatitis is another uncommon complication.⁸³⁰ In adult cases, there is a relatively high incidence of renal involvement.⁸³¹ The European League Against Rheumatism/Pediatric Rheumatology International Trials Organization/Pediatric Rheumatology European Society (EULAR/PRINTO/PRES) validated classification for Henoch-Schönlein purpura includes lower limb-predominant purpura and petechiae and one of the four following criteria: abdominal pain, histopathologic findings of IgA vessel deposits, arthritis or arthralgia, or renal involvement.⁸³² The rash may also be macular, papular, urticarial, and, rarely, vesiculobullous.⁸³³⁻⁸³⁶ Vesiculobullous lesions may occur on the lips and buccal mucosa.⁸³⁷ Redness, swelling, and limb pain accompanied by Raynaud's syndrome have been reported in a recent case.⁸³⁸ The bullae may be hemorrhagic.^{839,840} It is usually preceded by an upper respiratory tract infection or the ingestion of certain drugs or foods, with the formation of IgA-containing complexes, which may precipitate in vessels in the skin and certain other organs.⁸⁴¹⁻⁸⁴³ The alternate complement pathway is thereby activated. Anticardiolipin antibodies⁸⁴⁴ and ANCA,^{845,846} both of IgA class, have been reported in Henoch-Schönlein purpura. However, IgA ANCA are present in only 10% of cases. They can be detected in a wide variety of other cutaneous vasculitides.⁸⁴⁷ Specific associations of Henoch-Schönlein purpura have included pregnancy,⁸⁴⁸ alcohol,⁸⁴⁹ α_1 -antitrypsin deficiency,⁸⁴⁶ *H. pylori* infection of the stomach,⁸⁵⁰ *Proteus mirabilis* urinary tract infection,⁸⁵¹ *Mycoplasma pneumoniae* infection,⁸⁵² other bacterial and viral infections^{852,853} including parvovirus,^{854,855} vaccinations,^{856,857} and drugs such as penicillin, ampicillin, vancomycin,⁸⁵⁸ clarithromycin,⁸⁵⁹ erythromycin, chlorpromazine, losartan,⁸⁶⁰ aspirin (acetylsalicylic acid),⁸⁶¹ erlotinib,⁸⁶² isotretinoin,⁸⁶³ and adalimumab.⁸⁶⁴ It has been reported in association with the periodic fever syndromes, including hyperimmunoglobulinemia D,⁸⁶⁵ and familial Mediterranean fever. Of interest is the finding of mutations in the *MEFV* gene, which causes familial Mediterranean fever, in some children in Israel with Henoch-Schönlein purpura.⁸⁶⁶ It has been associated with malignancy in adults.⁸⁶⁷ In one case, Henoch-Schönlein purpura was mimicked by brucellosis.⁸⁶⁸ Henoch-Schönlein purpura has a predilection for children, although occurrence in adults is known.^{842,869-871} It has been reported in two siblings who had simultaneous onset but no obvious underlying infection.⁸⁷²

The disease usually runs a self-limited course, although in a small percentage of patients persistent renal involvement occurs. Pulmonary involvement is a rare complication of Henoch-Schönlein purpura.⁸⁷³

The role of corticosteroids in the treatment of this disease remains controversial. Although they do not appear to alter the course of the disease, they alleviate symptoms⁸⁷⁴ and may be of benefit in cases of ulcerative and extensive disease. They appear to offer a protective effect for nephritis, and they may modify accompanying arthritis and gastrointestinal disease.⁸⁴⁸

The condition reported as **infantile acute hemorrhagic edema** of the skin (Finkelstein's disease) is a closely related condition.⁸⁷⁵⁻⁸⁸⁰ Infants present with rounded, red to purpuric plaques, sometimes with a targetoid appearance, over the cheeks, ears, and extremities, associated with nonpitting acral edema. Low-grade fever may be present, but involvement of organ systems is minimal and laboratory studies are often unrevealing; recovery typically occurs within 1–3 weeks.⁸⁸¹ Approximately 300 children (median age, 11 months) have been reported with this condition.^{882,883} Rare cases have been reported in adults.⁸⁸⁴ It has followed cytomegalovirus infection,⁸⁸⁵ herpes simplex stomatitis,⁸⁸⁶ rotavirus infection,⁸⁸⁷ and measles⁸⁸⁸ and H1N1⁸⁸⁹ vaccination. In one report, infantile acute hemorrhagic edema was a presenting feature of the Wiskott–Aldrich syndrome.⁸⁹⁰ The histopathology is the same, although IgA deposition is not a predictable feature.⁸⁹¹⁻⁸⁹³ It has a benign course, leading to the suggestion that it be considered a separate entity.^{894,895} Both systemic corticosteroids and antihistamines have been used to treat this condition, but there is no evidence that they do any good, although a rapid response has been achieved in a few patients.⁸⁹⁵

Histopathology

The appearances are usually indistinguishable from those seen in leukocytoclastic vasculitis. IgA, predominantly of the IgA1 subclass,⁸⁹⁶ is demonstrable in vessel walls in both involved and uninvolved skin in most cases, provided that the biopsy is taken early in the course of the disease.^{841,842} It has been suggested that the punch biopsy should be taken from the edge of a fresh lesion to maximize the chances of finding IgA deposits.⁸⁹⁷ Lesions should be less than 48 hours in duration.⁸⁹⁸ Apoptotic dendrocytes (factor XIIIa positive) were noted around vessels in one case.⁸⁹⁹

Henoch–Schönlein purpura is not synonymous with IgA-associated vasculitis. Rather, it is one subcategory of it. An IgA vasculitis has been seen, without the usual clinical features of Henoch–Schönlein purpura, in a setting of prior infection, usually of the upper respiratory tract, in Wegener's granulomatosis, inflammatory bowel disease, and malignancies.⁹⁰⁰ IgA vasculitis and nephropathy have followed *Bartonella henselae* infection.⁹⁰¹ IgA deposits in superficial dermal vessels have also been reported in patients with evidence of alcohol abuse; the frequency of these deposits apparently does not differ when comparing patients with and without IgA nephritis.⁹⁰²

EOSINOPHILIC VASCULITIS

Eosinophilic vasculitis is a recently identified form characterized by an eosinophil-predominant necrotizing vasculitis affecting small dermal vessels.⁹⁰³⁻⁹⁰⁵ It presents with pruritic, erythematous, and purpuric papules and plaques. It may be idiopathic or associated with connective tissue diseases, the hypereosinophilic syndrome,^{903,906-908} or HIV infection.⁹⁰⁹

Treatment with systemic corticosteroids is usually effective, but recurrences are common.⁹¹⁰ Tacrolimus can improve the clinical manifestations and decrease the corticosteroid dosage needed to control the disease.⁹¹¹ In one case, the addition of suplatast tosilate, a dimethylsulfonium agent, was required to produce resolution.⁹¹²

Histopathology

There is a necrotizing, eosinophil-rich vasculitis involving small vessels in the dermis and, sometimes, the subcutis (Fig. 8.9). It involves a

Figure 8.9 (A) Eosinophilic vasculitis. (B) Eosinophils are a prominent component of the infiltrate. The patient had rheumatoid arthritis. Interestingly, urticaria is more conspicuous than in the case of urticarial vasculitis shown in Fig. 8.10. (H&E)

smaller class of vessel than Churg–Strauss syndrome. There is marked deposition of eosinophil granule major basic protein in the vessel walls.^{904,913}

RHEUMATOID VASCULITIS

Rheumatoid vasculitis is an uncommon but potentially catastrophic complication of rheumatoid arthritis.⁹¹⁴ It typically occurs in patients with seropositive, erosive rheumatoid arthritis of long standing with other extra-articular manifestations.⁹¹⁵⁻⁹¹⁷ A similar vasculitis may occur in some cases of SLE, mixed connective tissue disease, Sjögren's syndrome, and, rarely, dermatomyositis and scleroderma. Rheumatoid vasculitis is an acute vasculitis that differs from leukocytoclastic vasculitis in its involvement of large as well as small blood vessels. This leads to varied clinical presentations that may include digital gangrene, cutaneous ulcers, and digital nail fold infarction as well as palpable purpura.⁸¹⁵ Involvement of the vasa nervorum can result in a neuropathy.⁹¹⁸

Other cutaneous manifestations of rheumatoid arthritis may also be present in patients with rheumatoid vasculitis. These have been reviewed elsewhere.^{919,920} Cryofibrinogenemia can contribute to the development of severe necrotic lesions in some individuals with rheumatoid vasculitis.⁹²¹

In rheumatoid vasculitis, lesions are often recurrent. The overall mortality may approach 30%.⁹¹⁵ Immune complexes appear to be involved in the pathogenesis.⁹¹⁸

Systemic corticosteroids and/or nonsteroidal immunosuppressive agents are the mainstay of treatment for rheumatoid vasculitis. Argatroban, which has antithrombin action, has been used successfully in a single case.⁹²² Other newer agents include rituximab,^{923,924} TNF- α antagonists,⁹²⁵ and anti-IL-6 receptor antibody.⁹²⁶

Histopathology^{915,918}

As previously mentioned, rheumatoid vasculitis is an acute vasculitis with involvement of several sizes of blood vessels.⁹¹⁴ The involvement of medium-sized muscular arteries may be indistinguishable from that seen in polyarteritis nodosa. In the skin, vessels in the lower dermis are sometimes involved, while superficial vessels may be spared. Intimal proliferation and thrombosis of vessels also occur.

Magro and Crowson described a broad spectrum of vascular lesions in a study of cutaneous lesions in 43 patients with rheumatoid arthritis.⁹²⁰ They include pauci-inflammatory vascular thrombosis, glomeruloid neovascularization, a “neutrophilic vasculitis of pustular, folliculocentric, leukocytoclastic, or benign cutaneous PAN types”, granulomatous vasculitis, lymphocytic vasculitis, and occlusive intravascular histiocytic foci, for which they proposed the term ‘RA-associated intravascular histiocytopathy’.⁹²⁰

Rheumatoid vasculitis should be distinguished from rheumatoid neutrophilic dermatosis, which is one of the neutrophilic dermatoses and as such has no vasculitis.

Vascular IgA deposition has been reported in several patients with rheumatoid vasculopathy.⁹²⁰

URTICARIAL VASCULITIS

Urticarial vasculitis is another clinical variant of vasculitis; the cutaneous lesions comprise urticarial wheals and/or angioedema, often with some associated purpura.^{622,630,927,928} Erythematous papules and plaques may also occur, and in one case the lesions had an erythema gyratum repens-like configuration.⁹²⁹ The wheals usually persist longer than is usual for chronic urticaria without vasculitis, and they may resolve leaving an ecchymotic stain. Massive subcutaneous hemorrhage has been reported.⁹³⁰ The lesions are often generalized without any predilection for the lower legs. Systemic involvement, including renal failure, may occur, and this is more likely in those with concurrent hypocomplementemia.^{623,624,931,932} A lupus erythematosus-like syndrome is sometimes present.^{933–936} Urticarial vasculitis has been reported in association with hepatitis B and C infection,^{937–939} *Mycoplasma pneumoniae* infection (with clinical features that fulfilled the Yamaguchi criteria for adult-onset Still’s disease),⁹⁴⁰ Sjögren’s syndrome, IgA myeloma, an IgM gammopathy (Schnitzler’s syndrome),⁹⁴¹ Castleman’s disease,⁹⁴² polycythemia rubra vera,⁹⁴³ SLE, mixed connective tissue disease,⁹⁴⁴ anticardiolipin antibodies,⁹³⁹ solar and cold urticaria,⁶²⁸ exercise,⁹⁴⁵ pregnancy,⁹⁴⁶ visceral malignancy,⁹⁴⁷ and following the use of certain drugs,^{948,949} including diltiazem,⁹⁵⁰ cocaine,⁹⁵¹ and simvastatin.⁹⁵² One report described a case associated with high serum levels of IgG4, mimicking IgG4-related disease.⁹⁵³ It may follow exposure to formaldehyde.⁹⁵⁴ It has also followed the use of intravenous immunoglobulin for the treatment of lymphoma.⁹⁵⁵ Methotrexate may exacerbate the condition.⁹⁵⁶

Investigation of a familial form of hypocomplementemic urticarial vasculitis syndrome revealed mutations in *DNASE1L3* (which encodes an endonuclease) – this having been previously associated with SLE.⁹⁵⁷ The initial event is the deposition of immune complexes and C3 in the postcapillary venules. Complement activation ensues; its ongoing activation forms the membrane attack complex that may cause damage to the endothelial cell membranes.^{958,959} At the cellular level,

Figure 8.10 Urticarial vasculitis. The inset shows a dermal vessel in more detail. (H&E)

eosinophils appear at an early stage, at least in exercise-induced urticarial vasculitis.⁹⁴⁵

Systemic corticosteroids are the treatment of choice. The IL-6 antagonist tocilizumab has been used successfully to treat a case associated with refractory lupus erythematosus that recurred following corticosteroid taper.⁹⁶⁰

Histopathology⁹⁶¹

The changes are similar to those seen in leukocytoclastic vasculitis, although there is usually prominent edema of the upper dermis. The inflammatory infiltrate is sometimes quite mild (Fig. 8.10). A variant with a lymphocytic vasculitis has been reported.⁶²⁹ This may be a heterogeneous entity. A study of 22 patients exhibiting prolonged urticaria with purpura and exhibiting the clinical features of urticarial vasculitis showed that 19 of the cases had a predominantly lymphocytic infiltrate on histology.⁹²⁸ Only 3 cases had a neutrophil-predominant infiltrate associated with a leukocytoclastic vasculitis.⁹²⁸ There were varying numbers of eosinophils. The infiltrate involved the superficial plexus in most cases. The authors concluded that the majority of their cases with clinical urticarial vasculitis had a lymphocytic vasculitis.⁹²⁸ Subsequent correspondence has refuted the suggestion that a lymphocytic vasculitis can be a manifestation of an urticarial vasculitis.⁹⁶² A case associated with *Mycoplasma pneumoniae* infection showed predominantly lymphocytic infiltrates around superficial dermal vessels, but with neutrophils located both within and around vessel walls.⁹⁴⁰

One study found that the hypocomplementemic cases often have a more diffuse neutrophilia and the deposition of immunoreactants in a granular pattern along the basement membrane zone.⁹⁶³ The authors suggested that these cases could represent a subset of SLE.⁹⁶³

MIXED CRYOGLOBULINEMIA

Mixed cryoglobulinemia was discussed previously in this chapter along with the monoclonal form (see p. 224). The histopathological changes are those of an acute vasculitis resembling leukocytoclastic vasculitis. In contrast to the monoclonal form, intravascular hyaline deposits are the exception, although they are sometimes found beneath areas of ulceration.

HYPERGAMMAGLOBULINEMIC PURPURA

Hypergammaglobulinemic purpura (Waldenström) is characterized by recurrent purpura, anemia, an elevated erythrocyte sedimentation rate, and polyclonal hypergammaglobulinemia.^{663,964} There is a significant association with autoimmune diseases, especially Sjögren's syndrome and lupus erythematosus.⁹⁶⁵⁻⁹⁶⁷ Antibodies to Ro/SSA antigen are often present.⁹⁶⁶

Histopathology

The changes are similar to those occurring in leukocytoclastic vasculitis.

HYPERIMMUNOGLOBULINEMIA D SYNDROME

The hyperimmunoglobulinemia (hypergammaglobulinemia) D syndrome (OMIM 260920) presents in early childhood with recurrent febrile attacks with abdominal distress, headache, and arthralgias.⁹⁶⁸ Skin lesions are common during the attacks.⁹⁶⁹ They may be erythematous macules, urticarial lesions, or erythematous nodules. Elevated immunoglobulin D levels are not restricted to this syndrome. Levels are not necessarily increased, particularly in the early stages of the disease.

The inheritance is autosomal recessive. The condition is caused by a mutation in the mevalonate kinase (MVK) gene on chromosome 12q24. The enzyme involved participates in the sterol biosynthesis pathway.⁹⁶⁸ How this relates to the pyrin superfamily, responsible for other autoinflammatory diseases, is unknown.⁹⁷⁰ The mutation is common in northern Europe. Approximately 50% of patients with this disease are of Dutch ancestry.⁹⁷¹

Henoch-Schönlein purpura has occurred in a child with this syndrome.⁸⁶⁵

Treatment with NSAIDs, statins, etanercept, or anakinra has been used.⁹⁷¹

Histopathology

The usual cutaneous changes are those of a mild acute vasculitis, which may be leukocytoclastic.^{969,972} The pattern may rarely mimic Sweet's syndrome, erythema elevatum diutinum, or a cellulitis.

SEPTIC VASCULITIS

Septic vasculitis, also referred to (somewhat erroneously) as non-leukocytoclastic vasculitis,⁹⁷³ is a variant of acute vasculitis seen in association with various septicemic states. These include meningococcal septicemia, gonococcal septicemia, *Pseudomonas* septicemia, streptococcal septicemia,⁹⁷⁴ infective endocarditis, particularly that due to *Staphylococcus aureus*,⁹⁷⁵ and some cases of secondary syphilis. Certain rickettsial infections can produce similar lesions.

Cutaneous lesions occur in 80% or more of cases of acute meningococcal infections.⁹⁷⁶ There are erythematous macules, nodules, plaques, and petechiae that may be surmounted with small pustules.^{976,977} There is a predilection for the extremities and pressure sites. Features of DIC are invariably present. Acute gonococcemia is exceedingly rare in comparison, although localized pustular lesions have been reported on the digits.^{978,979} In *Pseudomonas* infections, hemorrhagic bullae, ulcers, and eschars are seen.^{980,981} These changes are discussed elsewhere as ecthyma gangrenosum (see p. 641). Acute pustular lesions also occur in infective endocarditis as Osler nodes and Janeway lesions.

Chronic infections with *Neisseria meningitidis* and *N. gonorrhoeae* are characterized by the triad of intermittent fever, arthralgia, and

Figure 8.11 Meningococcal septicemia. A vessel is occluded by a fibrin thrombus. There are some neutrophils in the surrounding dermis. (H&E)

vesiculopustular or hemorrhagic lesions.⁹⁸²⁻⁹⁸⁴ In chronic gonococcal septicemia, there is a marked female preponderance and lesions are fewer in number than in chronic meningococcal septicemia. Positive blood cultures have been obtained during febrile episodes.

A septic vasculitis can also involve larger vessels than in the vasculitides previously discussed. Femoral artery catheterization is one such cause. Risk factors for septic endarteritis in these circumstances include repeat puncture, indwelling sheath for more than 24 hours, and hematoma formation associated with the procedure.⁹⁸⁵

Histopathology

In *acute meningococcal septicemia*, there is widespread vascular damage characterized by endothelial swelling and focal necrosis, fibrinoid change in vessel walls, and occlusive thrombi composed of platelets, fibrin, red blood cells, and neutrophils (Fig. 8.11).^{986,987} There are neutrophils in and around vessel walls, as well as in the interstitium. Leukocytoclasia is often present, although it is usually quite mild.⁹⁷⁶ There is also some perivascular hemorrhage. The adnexa may show degenerative changes.⁹⁸⁶ Subepidermal edema and pustulation occur as well as intraepidermal pustules.⁹⁸⁶ Large numbers of gram-negative diplococci are seen in endothelial cells and neutrophils.^{986,987}

In *chronic meningococcal septicemia* and *chronic gonococcal septicemia*, there is a vasculitis that differs from hypersensitivity vasculitis in subtle ways. Arterioles are often affected in addition to venules, and deep vessels may show changes just as conspicuous as those in the superficial dermis. Extravasation of erythrocytes is often conspicuous. There is also an admixture of mononuclear cells in chronic septic vasculitis, and vascular thrombi are more regularly seen (Fig. 8.12).^{982,983} Leukocytoclasia is often present, but it is not a prominent feature.⁹⁸⁸ Another distinguishing feature is the regular presence of subepidermal and intraepidermal pustules with partial destruction of the epidermis.^{982,989} Organisms are usually not found with a Gram stain of tissue sections, although bacterial antigens are commonly identified using immunofluorescence techniques.^{982,989}

There are conflicting reports on the histopathological findings in the Osler nodes and Janeway lesions of infective endocarditis. Osler nodes appear to be a septic vasculitis, involving in part the glomus apparatus (Fig. 8.13),⁹⁹⁰ whereas Janeway lesions have variously been regarded as a similar process^{991,992} or as an embolic suppurative process with or without vasculitis.⁹⁹³⁻⁹⁹⁵ The histology of Osler nodes may also depend on the organism involved. The histology may sometimes be the usual type of leukocytoclastic vasculitis.⁹⁹⁶ Organisms have been found in the

Figure 8.12 Gonnococcemia. There are both thrombosis and leukocytoclastic vasculitis in this example. (H&E)

septic microemboli of Janeway lesions.^{997,998} Similar lesions, but without organisms, can be seen in marantic endocarditis.⁹⁹⁹

ERYTHEMA ELEVATUM DIUTINUM

Erythema elevatum diutinum is a rare dermatosis in which there are persistent red, violaceous, and yellowish papules, plaques, and nodules that are usually distributed acral and symmetrically on extensor surfaces, including the buttocks.¹⁰⁰⁰ The penis was involved in two cases.^{1001,1002} Pedunculated lesions^{1003,1004} and nodules surmounted by vesicles and bullae have also been described.^{1005–1008} Plantar vegetating and verrucous plaques are rare.¹⁰⁰⁹ Fibrotic nodules characterize lesions of long duration.¹⁰¹⁰ Arthralgia,¹⁰⁰⁰ peripheral ulcerative keratitis,¹⁰¹¹ scleritis,¹⁰¹² and pulmonary infiltrates¹⁰¹³ may occur. An association with myelodysplastic syndrome,^{1002,1014} lymphoma,¹⁰¹⁵ breast carcinoma,¹⁰¹⁶ multiple myeloma, IgA monoclonal gammopathy,^{1017–1021} hyperimmunoglobulinemia D syndrome,¹⁰²² antiphospholipid antibodies,¹⁰²³ and cryoglobulinemia¹⁰²⁴ has been documented. It has also been reported in association with celiac disease,^{1025,1026} ulcerative colitis,¹⁰²⁷ Crohn's disease,¹⁰²⁸ Hashimoto's thyroiditis,¹⁰²⁹ mosquito bites,¹⁰³⁰ relapsing polychondritis,^{1002,1031} SLE,¹⁰³² and lupus panniculitis,¹⁰³³ rheumatoid arthritis,^{1034,1035} dermatomyositis,¹⁰³⁶ HIV and HHV-6 infections,^{1037–1044} and pyoderma gangrenosum.¹⁰⁴⁵ In one case, erythema elevatum diutinum was associated with microscopic polyangiitis, myeloperoxidase ANCA, and accelerated interstitial pulmonary fibrosis.¹⁰⁴⁶ Onset is usually in middle life. Lesions may involute after 5–10 years, but persistence for 20 years has been reported.

The etiology is unknown, but erythema elevatum diutinum is thought to be a variant of leukocytoclastic vasculitis resulting from an Arthus-type reaction to bacterial and even viral antigens.¹⁰⁴⁷ Various cytokines, such as IL-8, allow a selective recruitment of leukocytes to involved sites.¹⁰⁴⁸ IgA class ANCAs are present in many cases;^{1049,1050} in fact, they have been found in all patients in published case series in which this finding has specifically been sought.¹⁰⁵¹ IgA ANCA positivity does not necessarily correlate with elevated serum IgA levels.¹⁰⁵¹ The formation of granulation tissue in lesions results in local perpetuation of the process because newly formed vessels are more vulnerable to injury.

The treatment of this disease is difficult because of its chronic and recurrent course. Dapsone or sulfonamides are first-line treatments.¹⁰⁵²

Figure 8.13 Osler's node. This lesion, from a patient with subacute bacterial endocarditis due to *Staphylococcus aureus*, shows changes of septic vasculitis, with both thrombosis and leukocytoclastic vasculitis. (H&E)

Dapsone in combination with cyclosporine has been used in one case.¹⁰⁵³ Tetracycline, colchicine, chloroquine, and corticosteroids (oral, topical, or intralesional) have been employed.¹⁰⁵² Topical dapsone in a 5% gel has been effective in localized disease.¹⁰⁵⁴ Surgery has been used successfully in advanced lesions.¹⁰⁵⁵

Histopathology^{1000,1056,1057}

Erythema elevatum diutinum is typically characterized by acute histological features that contrast with the chronic clinical course.¹⁰⁵⁸ Nevertheless, the histological appearances vary somewhat according to the age of the lesion.

In early lesions, there is a moderately dense perivascular infiltrate of neutrophils, with deposits of fibrin ("toxic hyalin") within and around the walls of small dermal blood vessels.^{1000,1004} These may also show endothelial swelling. Leukocytoclasia is also present. There are lesser numbers of histiocytes and lymphocytes and only a few eosinophils (**Fig. 8.14A**). Necrotizing granulomas were reported in one case.¹⁰³⁰ Extravasation of red cells is uncommon.

In more established lesions, the infiltrate of neutrophils involves the entire dermis. The epidermis is usually uninvolved, but there may be focal spongiosis. In vesiculobullous lesions, there is subepidermal vesiculation and pustulation.¹⁰⁰⁵ In another case, there were intraepidermal vesiculation and papillary dermal edema.¹⁰⁰⁷ Focal epidermal necrosis is sometimes present.¹⁰⁰⁵ Basophilic nuclear dust may encrust collagen bundles in some cases.¹⁰⁵⁶ Capillary proliferation is usually present in established lesions. In one instance, this resembled a pyogenic granuloma.¹⁰³⁰ Microscopic findings were similar in a case with oral ulceration.¹⁰⁵⁹

In late lesions, there is variable fibrosis and in some instances a fascicled proliferation of spindle cells.^{1034,1056} The low-power picture resembles a dermatofibroma. Small foci of neutrophilic vasculitis are scattered through the fibrotic areas (**Fig. 8.14B**).¹⁰⁰⁴ Capillary proliferation is also present. Extracellular cholesterosis of the older literature¹⁰⁵⁸ is now regarded as a variant in which lipids are secondarily deposited within macrophages and other cellular elements and possibly between the collagen.^{1060,1061} Since the introduction of dapsone in the treatment of this entity, cholesterol deposits no longer seem to be recorded.

Although immunoglobulins and complement have been reported in the vicinity of small vessels in the dermis, this has not been an

Figure 8.14 Erythema elevatum diutinum. (A) Early lesion. An angiocentric neutrophilic infiltrate with leukocytoclasia is observed. (H&E) (B) Late lesion. This lesion shows fibrosis, cholesterol cleft formation, and scattered neutrophils. (H&E)

invariable finding.¹⁰⁰⁰ Factor XIIIa-positive dendrocytes are present in the dermis, but in similar numbers to that seen in ordinary acute leukocytoclastic vasculitis.¹⁰⁶²

Electron microscopy

In addition to the fibrin deposition and neutrophil fragmentation, there are histiocytes present that contain fat droplets and myelin figures.¹⁰⁵⁶ Cholesterol crystals have been present in some cases, both intracellular and extracellular in position.¹⁰⁵⁶ Langerhans cells are increased in the dermis in both early and late lesions.¹⁰⁶³

Differential diagnosis

Although the clinical features are quite distinct, the histological features of early lesions may be indistinguishable from the neutrophilic dermatoses – Sweet's syndrome, rheumatoid neutrophilic dermatosis, the bowel-associated dermatosis–arthritis syndrome, and Behçet's disease. A case with overlap features between erythema elevatum diutinum and palisaded neutrophilic granulomatous dermatitis has been reported.¹⁰³⁵ Erythema elevatum diutinum differs from granuloma faciale in the predominance of neutrophils rather than eosinophils and the involvement of the adventitial dermis that is spared

in granuloma faciale (see later).¹⁰⁵⁶ In a comparative study of the latter two disorders by Ziemer and colleagues, using a checklist of 26 criteria, the histopathologic findings of erythema elevatum diutinum and granuloma faciale were found to be quite similar, differing only in four areas: the more frequent high-density infiltrates in granuloma faciale, the predominance of eosinophils in the majority of cases of granuloma faciale, the greater frequency of plasma cells in granuloma faciale, and – ironically – the presence of granulomatous nodules in 22% of erythema elevatum diutinum lesions but in none of the cases of granuloma faciale.¹⁰⁶⁴ Although, in late stages, erythema elevatum diutinum typically displays profound fibrosis, concentric perivascular fibrosis has also been described in granuloma faciale, suggesting a link between these two disorders. In fact, lesions with some microscopic elements of granuloma faciale or erythema elevatum diutinum but with more varied histopathologic features can present in a variety of clinical locations other than skin, and these have been grouped under the term 'localized chronic fibrosing vasculitis' (discussed later).

GRANULOMA FACIALE

Granuloma faciale is a rare dermatosis that manifests as one or several brown-red plaques, nodules, or sometimes papules on the face.^{1065–1068} Because lesions are often solitary, it may be misdiagnosed clinically as a neoplasm.¹⁰⁶⁹ In one case, the lesions were rhinophyma-like.¹⁰⁷⁰ There is a predilection for white males of middle age.¹⁰⁷¹ Childhood cases occur.¹⁰⁷² Extrafacial involvement is quite uncommon^{1073–1078} but continues to be reported;^{1079–1083} in that setting, distinction from erythema elevatum diutinum can be difficult.¹⁰⁸⁰ Disseminated disease is rare.^{1079,1084} The lesions are usually persistent and essentially asymptomatic. Its association with adenocarcinoma of the prostate may have been fortuitous.¹⁰⁸⁵ Several cases of granuloma faciale have been associated with angiocentric eosinophilic fibrosis of the larynx and upper respiratory tract mucosa.^{1086–1089}

The etiology is unknown, but a form of vasculitis, mediated by a localized Arthus-like process, has been postulated.¹⁰⁹⁰ The lymphocytic component of the infiltrate is thought to be attracted to the skin by IFN- γ -induced mechanisms.¹⁰⁹¹ There is a clonally expanded population of CD4⁺ lymphocytes. IL-5 production is increased.¹⁰⁹² Because some cases are associated with abnormal numbers of IgG4⁺ plasma cells, and in addition show obliterative vascular inflammation and 'storiform sclerosis', it has been proposed that granuloma faciale might represent a localized form of IgG4-related sclerosing disease.¹⁰⁹³

Numerous forms of treatment have been used, including topical corticosteroids, PUVA therapy, dapsone, antimalarials, and colchicine, but none has been consistently efficacious.¹⁰⁹⁴ Laser therapy has been effective in some reports¹⁰⁷⁰ but not in others.¹⁰⁹⁵ Topical tacrolimus 0.1% ointment has been tried with a successful outcome.^{1094,1096–1099} Cryotherapy has been advocated as a method of treatment.¹¹⁰⁰

Histopathology^{1065,1101}

There is usually a dense, polymorphous, inflammatory cell infiltrate in the upper two-thirds of the dermis, with a narrow, uninvolved grenz zone beneath the epidermis and often around pilosebaceous follicles (Fig. 8.15). Occasionally, the entire dermis and even the upper subcutis are involved.¹¹⁰² Sometimes the infiltrate is less dense and then tends to show perivascular accentuation. The infiltrate consists of eosinophils, usually quite numerous, together with neutrophils, lymphocytes, histiocytes, and a few mast cells and plasma cells. Eosinophils are sometimes absent.¹¹⁰³ Neutrophils are usually localized around the blood vessels, and there may be mild leukocytoclasia. There is controversy regarding whether neutrophils are related to the intensity of the inflammation or the stage of the disease.^{1065,1101} They appear to be related to early disease. A few foam cells and foreign body giant cells may be present.¹⁰⁹⁰ In lesions of long standing, there is usually some

Figure 8.15 Granuloma faciale. (A) A grenz zone of uninvolved dermis overlies a mixed inflammatory cell infiltrate. (B) A small amount of fibrin is present in vessel walls. The dermal infiltrate is more widespread than in most cases of hypersensitivity vasculitis. (C) There is a mixed inflammatory cell infiltrate surrounding a dermal blood vessel. (H&E)

fibrosis. It may be concentric around small blood vessels, similar to that seen in erythema elevatum diutinum.¹¹⁰⁴

Blood vessels in the upper dermis are usually dilated, often with some endothelial swelling. Eosinophilic fibrinoid material, so-called 'toxic hyalin', may be deposited around some vessels, but many cases do not show this feature. The material is PAS positive and diastase resistant. Extravasated red blood cells are often present, and hemosiderin is present in more than half of all biopsies. There is less red cell extravasation than in the usual acute vasculitis. A true vasculitis may be present, but this presumably depends on the timing of the biopsy with respect to the course of the disease process.¹¹⁰² Vessel wall necrosis has been described.¹¹⁰³ Dermoscopic findings parallel those seen microscopically and include dilated follicular orifices; linear, slightly arborizing vessels in parallel arrangement; and brown dots or globules probably reflecting hemosiderin deposition.¹¹⁰⁵

Immunoglobulins, particularly IgG, and complement are often present along the basement membrane and around blood vessels.¹¹⁰⁶ The basement membrane zone deposits have a granular appearance and may resemble the pattern seen in lupus erythematosus.¹¹⁰⁷ The perivascular deposits are sometimes heavy.¹¹⁰⁸ Fibrin is usually present around the vessels, even when toxic hyalin is not present on light microscopy.¹¹⁰⁶ Abundant eosinophilic cationic protein can be demonstrated in the dermis using immunohistochemistry.¹¹⁰⁹

Erythema elevatum diutinum (discussed previously) has many histological similarities, but in this condition the proportion of neutrophils to eosinophils is higher than in granuloma faciale and there is usually no well-defined grenz zone.¹¹⁰¹ Toxic hyalin is more abundant and often intimately related to the vessel wall in erythema elevatum diutinum.¹¹¹⁰

Electron microscopy

Electron microscopy reveals abundant eosinophils, often with cytoplasmic degenerative changes.¹¹¹¹ Charcot-Leyden crystals are commonly seen.

LOCALIZED CHRONIC FIBROSING VASCULITIS

The term 'localized chronic fibrosing vasculitis' was used by Carlson and LeBoit for a solitary lesion whose histology resembled late-stage erythema elevatum diutinum or granuloma faciale, but with a clinical picture that resembled neither.¹¹¹² The lesions were red-brown, violaceous papules, plaques, and nodules that had been present for several months.

Histopathology¹¹¹²

The lesions combined variable amounts of patterned fibrosis (storiform, concentric, or lamellar) and inflammation that was nodular or diffuse.

Focal leukocytoclastic vasculitis was usually present. Both neutrophils and eosinophils were present in varying numbers with admixed lymphocytes and aggregates of plasma cells. In some parts, the lesion resembled inflammatory pseudotumor and in other areas a sclerotic fibroma.

MICROSCOPIC POLYANGIITIS (POLYARTERITIS)

Microscopic polyangiitis is a systemic small vessel vasculitis associated with focal and segmental glomerulonephritis and the presence of circulating antibodies to one of the antineutrophil cytoplasmic antibodies (perinuclear ANCA (p-ANCA)). There are few, if any, immune complexes deposited in vessel walls.¹¹¹³ It affects predominantly middle-aged males. Constitutional symptoms are usually present, and

pulmonary involvement (capillaritis) is not uncommon.^{1114,1115} Skin, nerves, and gastrointestinal tract are other sites of involvement.¹¹¹⁶

Cutaneous lesions are present in 30–60% of cases and comprise the initial presenting finding in up to 30% of cases.¹¹¹⁶ They are usually purpuric lesions on the lower limbs; necrotic ulcers are uncommon and nodules are rare.¹¹¹⁴ In one series of eight patients, all cases presented with erythematous macules on their extremities.¹¹¹⁷ Livedo reticularis was present in five of the patients. Urticarial lesions have also been reported. The condition has been associated with systemic sclerosis,¹¹¹⁸ antiphospholipid antibodies,¹¹¹⁹ and giant cell arteritis.^{1120,1121}

Similar cases have been classified in the past as hypersensitivity vasculitis with systemic involvement or included with polyarteritis nodosa.

The disease generally has a rapidly progressive clinical course, but there have been reports of slowly progressive cases.¹¹¹⁷ These slowly progressive cases seem to have less severe neutrophil infiltrates in the biopsy and more superficial dermal vascular involvement.¹¹¹⁷

Histopathology¹¹¹³

There is an acute (neutrophilic) vasculitis with variable leukocytoclasia, accompanied by extravasation of red blood cells and patchy fibrinoid degeneration of vessels. Characteristically, the process involves arterioles, but capillaries and postcapillary venules may also be involved. It spares medium-sized muscular arteries. The uncommon nodular lesions show a heavy mixed inflammatory cell infiltrate, particularly in the lower dermis and upper subcutis, and an accompanying vasculitis in these deeper foci. Direct immunofluorescence studies are sometimes negative or only show few deposits of immunoglobulin or complement.^{1122,1123} The specificity of ANCA in defining a subset of patients with leukocytoclastic vasculitis has been challenged.¹¹²⁴ Despite these reservations, a cutaneous-limited variant associated with antimyeloperoxidase autoantibodies has been suggested.¹¹²⁵

A microscopic polyangiitis may occur in the Epstein-Barr virus infections associated with mosquito-bite hypersensitivity prior to the development of natural killer/T-cell lymphoma with angiodestruction.¹¹²⁶

A study from France, comparing the clinical and histological features of *systemic* polyarteritis nodosa and microscopic polyangiitis, concluded that neither the clinical nor the histological features were helpful in distinguishing these two conditions.¹¹²³

Differential diagnosis

Such cases may be difficult to distinguish from Wegener's granulomatosis, but granulomas and upper airway involvement are absent in microscopic polyangiitis. Furthermore, Wegener's granulomatosis is usually associated with cytoplasmic ANCA (c-ANCA), although p-ANCA is sometimes found. These two conditions are part of a spectrum of ANCA-associated disease.¹¹²⁷ Artificial neural network (ANN) and more traditional classification tree (CT) approaches have been shown to be accurate means of distinguishing between these two disorders.¹¹²⁸ It may also be difficult to distinguish microscopic polyangiitis from polyarteritis nodosa. Cutaneous manifestations can be similar, as can the histopathologic findings. Although polyarteritis nodosa is less likely to have small vessel vasculitis and more likely to show arteriolar involvement, there is significant overlap in these findings. Therefore, a constellation of features other than those in skin biopsies is generally required to allow differentiation: these include ANCA status (negative in polyarteritis nodosa), pulmonary infiltrates or glomerulonephritis (significantly more frequent in microscopic polyangiitis), and evidence for digestive tract or renal microaneurysms or stenoses (a feature in many cases of polyarteritis nodosa, not found in microscopic polyangiitis).

POLYARTERITIS NODOSA

Polyarteritis nodosa is a rare inflammatory disease of small and medium-sized muscular arteries. It usually involves multiple organs,^{1129–1131} including the kidneys, liver, gastrointestinal tract, and nervous system. The skin is involved in approximately 10–15% of cases, resulting in palpable purpura and sometimes ulceration of the lower extremities.¹¹³² There are usually constitutional symptoms such as fever, weight loss, fatigue, arthralgia, and myalgia.¹¹²⁹ Selective IgA deficiency was present in one case.¹¹³³ No age is exempt, but there is a predilection for adult males.

The course is variable, but it is not possible to predict those likely to develop progressive disease.¹¹²⁹ The 5-year survival rate is approximately 50%; death is usually the result of involvement of the kidneys or gastrointestinal tract.¹¹²⁹

A **cutaneous form of polyarteritis nodosa**, with a chronic relapsing course but usually no evidence of systemic disease, has been reported.^{1134–1137} Renal involvement was reported in one series.¹¹³⁸ This variant usually presents with edema and nodules, often painful, livedo reticularis, or ulceration involving the lower limbs.^{1139,1140} Sometimes cases present as atrophie blanche.¹¹⁰⁹ There may be mild constitutional symptoms such as fever. They often have a recurrent and chronic course over decades, but the prognosis is nevertheless good.^{1141,1142} An unusual complication has been the formation of periosteal new bone beneath the cutaneous lesions.¹¹⁴³ A variant localized to the breast has been reported.¹¹⁴⁴ A number of childhood examples have been reported; musculoskeletal involvement has been common in these cases.¹¹⁴⁵

There are probably many causes of polyarteritis nodosa. Immune complexes appear to play an important role in the pathogenesis. Angiogenic cytokines (basic fibroblast growth factor and vascular endothelial growth factor) are increased in polyarteritis nodosa, more so in the systemic than the cutaneous form.¹¹⁴⁶ Hepatitis B surface antigen has been detected in up to 50% of systemic cases,¹¹⁴⁷ but this percentage is much higher than has been recorded in most series.¹¹⁴⁸ The antigen has also been reported in the localized cutaneous form.^{1138,1149–1151} Hepatitis C infection has been present in some cases.¹¹⁵² Preceding bacterial infections, particularly streptococcal, have been documented in both types, and it appears to be a frequent association in childhood cutaneous cases.^{1153–1155} There is one report of cutaneous polyarteritis nodosa induced by *M. tuberculosis*.¹¹⁵⁶ Most of the cutaneous cases reviewed at the Mayo Clinic were idiopathic.¹¹³⁹

Although cutaneous polyarteritis nodosa is found to be ANCA-negative using direct or capture enzyme-linked immunosorbent assay methods, ANCA has been detected in these patients using an indirect immunofluorescence assay; both p-ANCA and atypical ANCA patterns have been identified.¹¹⁵⁷ Patients with p-ANCA in this context have significantly elevated levels of anti-lysosomal-associated membrane protein-2 antibody levels – a feature of some primary vasculitides.¹¹⁵⁷

Polyarteritis nodosa-like lesions have been reported in association with Crohn's disease,¹¹⁵⁸ Fabry's disease,¹¹⁵⁹ sickle cell disease,¹¹⁶⁰ B-cell lymphoma,¹¹⁶¹ Kawasaki syndrome (see later), myasthenia gravis,¹¹⁶² rheumatoid arthritis, angioimmunoblastic lymphadenopathy, and following the repair of coarctation of the aorta.¹¹⁶³ They have also been noted following the intravenous injection of methamphetamine (methamphetamine, 'speed')¹¹⁶⁴ and following the prolonged use of minocycline in the treatment of acne.^{1165,1166}

Macular arteritis is an indolent, deep arteritis characterized by hyperpigmented macules that are asymptomatic and show no tendency for progression.^{1167,1168} It has been reported in rheumatoid arthritis.¹¹⁶⁹ It has been suggested that this condition is a latent form of cutaneous polyarteritis nodosa with a most unusual clinical presentation and a histological pattern (see later) at the chronic/healed end of the spectrum of polyarteritis nodosa.^{1170,1171} Lee, Kossard, and McGrath

suggested the term ‘**lymphocytic thrombophilic arteritis**’ for this condition.^{1172,1173}

The treatment of cutaneous polyarteritis includes topical corticosteroids under occlusion, oral corticosteroids, with or without azathioprine or mycophenolate mofetil.¹¹⁴⁰ Methotrexate, dapsone, colchicine, and cyclophosphamide have also been used.¹¹⁴² A recent case was successfully treated with infliximab.¹¹⁷⁴ Warfarin has also been useful in the management of some cases.¹¹⁷⁵ Antimicrobial therapy is used in patients (particularly children) with preceding streptococcal infection, and prophylaxis is used when relapses are tied to recurrent infections.¹¹⁷⁶

Histopathology¹¹⁷⁷

Because the initial biopsy in approximately one-third of cases is nondiagnostic, it is important that a deep biopsy to include subcutis is taken. If an ulcer is present, it is best to take the biopsy from near the ulcer center and not from the periphery of the ulcer.¹¹⁷⁸ In the early stages, there is marked thickening of the wall of the vessel, particularly the intima, as a result of edema and a fibrinous and cellular exudate. The infiltrate is composed of neutrophils, with some eosinophils and lymphocytes. Leukocytoclasia is sometimes present. In older lesions, there is a greater proportion of mononuclear cells, particularly lymphocytes. Luminal thrombi and aneurysms may form. Initially, the lesions are segmental, but the infiltrate expands to involve the full circumference of the artery. The changes are often localized to the region of a bifurcation of the vessel. At a still later stage, there is intimal and mural fibrosis leading to obliteration of the vessel. A characteristic feature of polyarteritis nodosa is the presence of lesions at all stages of development.¹¹⁷⁹

In the *cutaneous form*, small and medium-sized arteries in the subcutis and occasionally the deep dermis are involved. The inflammation is localized to the vessel and its immediate vicinity, allowing a distinction to be made from the various panniculitides (Fig. 8.16). There may be a mild perivascular lymphocytic infiltrate in the overlying dermis.

In *macular arteritis* (*lymphocytic thrombophilic arteritis*), large arteries at the dermal-subcutaneous junction and smaller vessels in the subcutis show nonspecific chronic inflammation. The main change is an endarteritis obliterans with fragmentation of the internal elastic lamina. A hyalinized fibrin ring with nuclear dust and inflammatory cell debris is present in the vessel lumen.^{1172,1180} Hemosiderin was

present in one case, but it has been specifically excluded in others.^{1168,1171} The cause of the pigmentation is not apparent.

Immunofluorescence of the cutaneous form of polyarteritis nodosa has shown IgM and sometimes C3 in the vessel walls.¹¹³⁴

Differential diagnosis

The microscopic differential diagnosis includes *thrombophlebitis* and its variants. Both conditions show neutrophilic infiltration of a prominent subcutaneous vessel. In our experience, biopsies of thrombophlebitis are more prone to show a mixed inflammatory infiltrate involving the vessel, including macrophages and even multinucleated giant cells. This in part probably reflects the relative duration of the lesions prior to biopsy, but different inflammatory mechanisms might also explain the differences. Traditionally, the presence or absence of an internal elastic lamina has been considered decisive in determining whether the involved vessel is an artery or a vein (with the presence of an internal elastic lamina indicating that the vessel is most likely an artery). However, internal elastic laminae are also found in larger veins. Studies by Dalton *et al.* indicate that a better way to distinguish between the two types of vessels is to examine the smooth muscle pattern of the vessel wall; veins show a ‘checkerboard’ arrangement of muscle intermingled with collagen, whereas arteries demonstrate a more concentric pattern of smooth muscle (Fig. 8.17). Combining assessments of both internal elastic lamina and smooth muscle pattern often enhances the accuracy of determining whether an involved vessel is an artery or a vein.¹¹⁸¹ However, even this approach can be problematic, especially when evaluating vessels in the lower legs and feet, where due to hydrostatic pressure, veins can display thick muscular layers with concentric arrangements and rounded lumina, thereby resembling arteries. To resolve this issue, Chen recommends analysis of the elastic fiber pattern within the muscular layer of the vessel; elastic fibers are sparse in the medial muscle layer in arteries, whereas they are abundant in this layer in veins, distributed between smooth muscle bundles.¹¹⁸²

KAWASAKI SYNDROME

Kawasaki syndrome (Kawasaki disease, mucocutaneous lymph node syndrome; OMIM 611775) is an acute, multisystem, febrile illness of unknown cause that occurs predominantly in infancy and early childhood.^{1183–1187} Adult cases have been reported,¹¹⁸⁸ but some of these may represent erythema multiforme or the toxic shock syndrome.¹¹⁸⁹ In the absence of a specific diagnostic test, diagnosis of adult cases requires a detailed assessment of the clinical features. One recently reported adult patient presented with splenomegaly and elevated serum ferritin levels.¹¹⁹⁰ In addition to the prolonged fever, clinical features include nonexudative conjunctivitis, cervical lymphadenopathy, oropharyngeal inflammation, thrombocytosis, and a vasculitis that predominantly involves the coronary arteries, leading to coronary artery aneurysms or ectasias in 20% or more of cases.^{1184,1191–1193} Facial nerve paralysis developed in one case.¹¹⁹⁴ In a review from Brazil, the most common complications included coronary aneurysms, sensorineural hearing loss, ataxia, and ophthalmic effects.¹¹⁹⁵ The disease is usually self-limited although recurrences have been reported,¹¹⁹⁶ and 1% may end fatally, almost exclusively from the cardiac involvement.

Cutaneous manifestations include a polymorphous, exanthematous rash accompanied by brawny edema and erythema of the palms and soles.^{1184,1191} This is followed by desquamation that particularly involves the tips of the fingers and toes. Recurrent skin peeling may continue for several years.¹¹⁹⁷ An erythematous, desquamating perineal eruption is a distinctive feature in many cases.¹¹⁹⁸ A pustular rash resembling miliaria pustulosa also occurs in some patients.¹¹⁹⁹ Psoriasis developed in another patient following Kawasaki disease.¹²⁰⁰ In another instance,

Figure 8.16 Cutaneous polyarteritis nodosa. The affected small arteries in the upper subcutis show marked fibrin extravasation into their walls. (H&E)

Figure 8.17 Differentiation between polyarteritis nodosa and superficial thrombophlebitis. (A) Polyarteritis nodosa; note the concentric pattern of smooth muscle in this arterial wall. (B) Superficial thrombophlebitis; the wall of the involved vein shows a 'checkerboard' arrangement of muscle intermingled with collagen. Analysis of the elastic fiber pattern within the muscular layer of the vessel may provide further help in distinguishing arteries from veins in difficult cases. (H&E)

psoriasiform skin lesions may have been produced or exacerbated by therapy with infliximab.¹²⁰¹ There has been a case complicated by cutaneous vasculitis and peripheral gangrene.¹²⁰² A transient maculopapular eruption, associated with low-grade fever and mildly elevated liver enzymes, has also been reported during the convalescent phase of Kawasaki disease patients, 10 days after receiving intravenous immunoglobulin (IVIG);¹²⁰³ however, this same type of eruption can apparently also occur following IVIG therapy in patients who have not had Kawasaki disease. Although the etiology is unknown, a microbial cause, possibly involving a bacterial superantigen,¹¹⁸⁸ is suggested by the clinical features, by the occurrence of epidemic outbreaks, and by the amelioration of coronary artery abnormalities by the use of gamma globulin.^{1204,1205} A retrovirus and *Propionibacterium acnes* have been suggested at one time or another, but no agent has been consistently demonstrable.¹²⁰⁶ Infection with HIV has rarely been present.¹²⁰⁷ Antiendothelial antibodies have been detected in some cases.¹²⁰⁸ Abnormalities of the cutaneous microcirculation have been identified

using Doppler flowmetry and dynamic capillaroscopy; the changes include abnormal capillary morphology and decreased capillary blood cell velocity.¹²⁰⁹

A genetic susceptibility to an infectious agent has been found. Initially, it was thought that an association with the *CD40LG* gene was involved, but in 2008 the same group found a functional polymorphism in the *ITPKC* gene on chromosome 19q13.2 that is associated with Kawasaki disease susceptibility and also with an increased risk of coronary artery lesions in both Japanese and U.S. children.¹²¹⁰

Treatment with aspirin and IVIG produced rapid resolution of the disease in several patients.^{1193,1205} Clopidogrel has been used as maintenance therapy.¹¹⁹³

Histopathology

Biopsies of the skin lesions are infrequently performed. They have shown nonspecific features that include edema of the papillary dermis and a mild perivascular infiltrate of lymphocytes and mononuclear cells.^{1191,1211} Subtle vascular changes, including subendothelial edema, focal endothelial cell necrosis, and vascular deposition of small amounts of fibrinoid material, were noted in one report.¹²¹¹ The pustular lesions are small intraepidermal and subcorneal abscesses; they are not related to eccrine ducts.¹¹⁹⁹

Synthetic antibodies derived from IgA antibody sequences in acute Kawasaki disease bind in the apical cytoplasm of ciliated bronchial epithelial cells (from patients but not controls) to intracytoplasmic inclusion bodies with features consistent with viral protein and nucleic acid; this material may provide clues to the etiologic agent or agents and permit development of a diagnostic test for the disease.¹²¹² Autopsies on fatal cases have shown a polyarteritis nodosa-like involvement of the coronary and some other visceral arteries. Cutaneous vasculitis of this degree has not been observed,¹¹⁸³ although small vessel leukocytoclastic vasculitis has been described.¹²⁰²

SUPERFICIAL THROMBOPHLEBITIS

Superficial thrombophlebitis presents with tender, erythematous swellings or cord-like thickenings of the subcutis, usually on the lower parts of the legs. Multiple segments of a vein may be involved over time, hence the use of the term 'migratory' in the older literature to describe this process. Superficial thrombophlebitis may occur in association with Behçet's disease, Buerger's disease (thromboangiitis obliterans), or an underlying cancer, most often a carcinoma of the pancreas or stomach.^{1213,1214} It may be associated with various hypercoagulable states.^{1215,1216} In one patient, the disease was associated with hypertension; it responded to antihypertensive therapy but not NSAIDs or corticosteroids.¹²¹⁷ Superficial thrombophlebitis has also developed as a manifestation of immune reconstitution inflammatory syndrome in response to highly active antiretroviral therapy.¹²¹⁸

Mondor's disease is a variant of superficial thrombophlebitis occurring in relation to the breast or anterolateral chest wall.^{1219–1224} A history of herpes zoster,¹²²⁵ preceding trauma, including body building,¹²²⁶ localized strain,¹²²⁷ and breast surgery is obtained in a number of cases. A review in 2008 concluded that although almost all cases of Mondor's disease are due to thrombophlebitis, a small minority are due to lymphangitis or other conditions.¹²²⁴

Histopathology

Sometimes difficulties are experienced in picking an artery from a vein, particularly in vessels from the lower leg where 'arterialized veins' can occur. As noted previously (see discussion of polyarteritis nodosa), the study by Dalton *et al.* indicates that the smooth muscle pattern may be more reliable than assessment of the internal elastic lamina.¹¹⁸¹ Whereas an artery generally has a continuous wreath of concentric

Figure 8.18 Superficial thrombophlebitis in Buerger's disease. There is focal suppuration of the vein wall and a luminal thrombus. There is some controversy regarding the specificity of this finding. (H&E)

smooth muscle, a vein has bundled smooth muscle fibers with intermixed collagen.¹¹⁸¹ According to Chen, analysis of the elastic fiber pattern within the muscular layer of the vessel may provide the best means of distinguishing veins from arteries in the lower legs and feet.¹¹⁸² A recent study by Hall, Dalton, and colleagues using amputation and autopsy specimens shows that although the elastic fiber pattern in muscular walls is the most specific feature in identifying a vein, the smooth muscle pattern has the highest combined sensitivity and specificity. On the other hand, in attempting to distinguish between superficial thrombophlebitis and arteritis when examining an inflamed vessel, each of the commonly used histopathologic criteria (internal elastic lamina, smooth muscle pattern, and elastic fiber pattern in muscular walls) becomes less reliable, with poor interobserver reliability. Therefore, clinicopathologic correlation is essential in making the correct interpretation.¹²²⁸

Superficial thrombophlebitis involves veins in the upper subcutis. In early lesions, the inflammatory cell infiltrate is composed of numerous neutrophils, although at a later stage there are lymphocytes and occasional multinucleate giant cells. Intramural microabscesses are commonly present in the vein in the thrombophlebitis that accompanies Buerger's disease; there is some controversy whether this finding is specific for this disease (Fig. 8.18). The inflammatory cell infiltrate extends only a short distance into the surrounding fat, in contrast to the more extensive panniculitis seen in erythema induratum–nodular vasculitis.

Thrombus is often present in the lumen of the affected veins, and this eventually undergoes recanalization.

SCLEROSING LYMPHANGITIS OF THE PENIS

Sclerosing lymphangitis of the penis is characterized by the sudden appearance of a firm, cord-like, nodular lesion in the coronal sulcus or on the dorsum of the shaft of the penis.¹²²⁹ It is usually asymptomatic and subsides after several weeks. Recurrences are documented. The etiology is unknown, but sexual intercourse,^{1230,1231} *Candida* infection,¹²³² herpes infection,¹²³³ tadalafil use,¹²³⁴ and secondary syphilis¹²³⁵ have been incriminated in some cases.¹²³⁶

Reassurance and sexual abstinence for several weeks is the suggested course of treatment. Surgical resection of lesions is not recommended unless they persist. Patients should be evaluated for any underlying sexually transmitted infection.¹²³⁶

Figure 8.19 Sclerosing lymphangitis of the penis. Condensed eosinophilic material fills the lumen of a vessel, most likely a vein. (H&E)

Histopathology^{1237,1238}

Established lesions show a dilated vessel, the lumen of which contains condensed eosinophilic material or a fibrin thrombus in the process of recanalization (Fig. 8.19). Lymphocytes and macrophages are often present within the thrombus. The wall of the vessel shows prominent fibrous thickening.¹²²⁹ There is usually a mild inflammatory cell infiltrate and some edema around the involved channel. The vessel is usually said to be a lymphatic, but the suggestion has been made that it is in fact a vein and that the condition may be likened to Mondor's phlebitis.^{1224,1239}

Electron microscopy

Small lymphatic capillaries containing lymphocytes form within the luminal thrombus.¹²³⁷ Newly formed collagen fibrils are present in the vessel walls.

MISCELLANEOUS ASSOCIATIONS

An acute vasculitis is a feature of erythema nodosum leprosum (see p. 662). It has also been reported in the rose spots of paratyphoid fever¹²⁴⁰ and in the Jarisch–Herxheimer reaction that may follow therapy for syphilis.¹²⁴¹ In this latter condition, the acute inflammatory changes are superimposed on a background of chronic inflammation in which plasma cells are usually prominent.¹²⁴¹

The condition known as erythema induratum–nodular vasculitis is also an acute vasculitis. It results in a panniculitis and accordingly is discussed with the panniculitides on page 535.

Rarely, a fixed drug eruption will present as a localized area of acute vasculitis. As in erythema elevatum diutinum, the upper dermis may contain many neutrophils despite the lesion being of some weeks' duration. No lichenoid features are present.

NEUTROPHILIC DERMATOSES

The neutrophilic dermatoses are a clinically heterogeneous group of entities characterized histopathologically by the presence of a heavy dermal infiltrate of neutrophils and variable leukocytoclasia.¹²⁴² On casual examination of tissue sections, the appearances suggest an acute vasculitis, although on closer inspection there is no significant fibrinoid

necrosis of vessel walls. Furthermore, the neutrophilic infiltrate is usually much heavier in the neutrophilic dermatoses than in leukocytoclastic vasculitis. Limited vascular damage in the form of endothelial swelling may be present, and in some biopsies fibrinoid necrosis of some vessel walls may be found. The term 'pustular vasculitis' has been proposed as an alternative designation, particularly for those cases in which there is evidence of a vasculitis – a sign of the confusion that surrounds the nosological classification of this group.^{1243,1244} Pustular vasculitis has also been reported in SLE¹²⁴⁵ and in a T-cell large granular lymphocyte proliferation.¹²⁴⁶

Circulating immune complexes with heightened chemotaxis of neutrophils are thought to have an important pathogenetic role.¹²⁴⁴ The immune complexes appear to be of diverse origin. Cytokines such as IL-1 may play a contributory role.¹²⁴⁷

The following diseases are considered in this category, but note that the lesions in some stages of Behçet's syndrome do not qualify for inclusion:

- Periodic fever syndromes (autoinflammatory diseases)
- Amicrobial pustulosis of the folds
- Sweet's syndrome (including pustular vasculitis of the hands and neutrophilic fixed drug eruption)
- Bowel-associated dermatosis–arthritis syndrome
- Rheumatoid neutrophilic dermatosis
- Acute generalized pustulosis
- Behçet's syndrome
- Abscess-forming neutrophilic dermatosis.

Although it has many histopathological features in common with this group, erythema elevatum diutinum has prominent fibrinoid change in vessel walls and is best included with the acute vasculitides. Pyoderma gangrenosum has also been included in this group by some authorities.⁶⁶⁰

Cohen reviewed the various neutrophilic dermatoses occurring in oncology patients and also the progressive or concurrent development of several of these diseases in the same patient.¹²⁴⁸ Others have also highlighted the concept of 'neutrophilic diseases'.^{1249,1250} Subcorneal pustular dermatosis, neutrophilic eccrine hidradenitis, erythema elevatum diutinum, and intraepidermal IgA pustulosis are additional categories of neutrophilic dermatoses that may occur alone or in association in oncology patients.^{1248,1251} Some of the pyodermic lesions seen in association with subclinical myelodysplastic syndrome do not fit any of the described neutrophilic dermatoses.¹²⁵² One such case had features of the SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteomyelitis) syndrome (see p. 462). Multiple neutrophilic dermatoses have also been reported in a child with glomerulonephritis.¹²⁵³

PERIODIC FEVER SYNDROMES (AUTOINFLAMMATORY DISEASES)

The periodic fever syndromes are an inherited group of disorders characterized by recurrent episodes of fever, systemic inflammation that often includes skin manifestations, and AA amyloidosis that varies in frequency in the different entities that comprise this group.^{971,1254} They are also known as autoinflammatory disorders because there is no evidence of any autoimmune or self-reactive T and B lymphocytes.⁸⁶⁶ Although Crohn's disease and Blau's syndrome (see p. 192) have been included as autoinflammatory syndromes, this account is restricted to other disorders, most of which involve the pyrin gene superfamily. Included is the prototype disorder familial Mediterranean fever due to mutations in the pyrin gene *MEVF*; the three cryopyrin diseases due to mutations in the *CIAS1* (human cold-induced autoinflammatory syndrome 1) gene, also known as *PYPAFI* or *NALP3*; the condition known as TRAPS (tumor necrosis factor receptor-associated

periodic syndrome) due to mutations in the gene (*TNFRS1A*) encoding the TNF1 receptor; PAPA, in which pyoderma gangrenosum, severe acne, and sterile arthritis are key features; and HIDS (hyperimmunoglobulinemia D syndrome), in which a defect in the *MVK* gene encoding mevalonate kinase is involved.^{866,971} The relationship of these latter three conditions to the pyrin superfamily is currently unknown. In the other diseases, there is interference in the caspase-1 and IL-1 β pathways leading to an increase in IL-1 β production. The IL-1 receptor antagonist, anakinra, is now being used as an effective treatment of these conditions. There are also responses to the IL-1 binding and neutralizing fusion protein (riloncept) and to humanized monoclonal antibody against IL-1 β (canakinumab).¹²⁵⁵

Rasheed syndrome, in which there is recurrent multifocal osteomyelitis and congenital dyserythropoietic anemia, is not included with the periodic fevers. However, it is characterized by fever, sometimes low grade, and a neutrophilic dermatosis, which has usually been regarded as Sweet's syndrome. It involves a mutation in the *LPIN2* gene.¹²⁵⁶ Some affected individuals and/or their relatives have psoriasis.¹²⁵⁶

The three diseases associated with mutations in the *CIAS/NALP3* gene that encodes cryopyrin share the periodic manifestation of symptoms.¹²⁵⁷ Their unique cutaneous feature is urticaria. The three diseases are (1) neonatal-onset multisystem inflammatory disorder (NOMID), in which there is severe expression of the phenotype; (2) Muckle-Wells syndrome, with intermediate expression of symptoms; and (3) familial cold-induced autoinflammatory syndrome (FCAS),¹²⁵⁴ with mild expression of the phenotype.¹²⁵⁷ This group of diseases is characterized by vascular dilatation, swelling of endothelial cells, mild urticarial changes, and margination of neutrophils around vessels with extension into the interstitium. Some margination of vessels with neutrophils also occurs around sweat glands.¹²⁵⁴ A perieccrine neutrophilic infiltrate (without infiltration of glandular epithelium or alteration of secretory cells) has also been reported in a case of NOMID.¹²⁵⁵ The term 'neutrophilic urticarial dermatosis' (NUD) has been applied to the three cryopyrin-related diseases and to HIDS.¹²⁵⁵

A summary of these syndromes is included in Table 8.3. Because familial Mediterranean fever most resembles a mild neutrophilic dermatosis, it is considered next.

Recent additions to the hereditary periodic fever syndromes include DIRA (deficiency of the IL-1 receptor antagonist,^{1258,1259} DITRA (deficiency of interleukin-36 receptor antagonist),¹²⁵⁸ and mutations in *NALP12*, part of a family of proteins (inflammasomes) involved in inflammatory signaling pathways.¹²⁶⁰ IL-1 blockade may be useful in treating DIRA cases, and there is evidence that it may also be useful in the management of pustular forms of psoriasis without this specific genetic abnormality.^{1258,1261} Regarding histopathologic features of these newly recognized syndromes, biopsies of DIRA patients of Puerto Rican descent (who harbor mutations in the founder gene *IL-1RN*) have shown subcorneal pustules and infundibulofolliculitis,¹²⁶² whereas DITRA patients have developed generalized pustular psoriasis and, in one case, acrodermatitis continua of Hallopeau.^{1258,1263} Mutations in *NALP12* have been associated with urticarial lesions.¹²⁶⁰

Familial Mediterranean fever (FMF)

Familial Mediterranean fever (OMIM 249100) is an autosomal recessive, autoinflammatory disease characterized by acute, self-limited attacks of fever, erysipelas-like erythema, abdominal pain, and serosal inflammation.^{1264,1265} It is the prototype of a group of inherited diseases referred to as hereditary periodic (recurrent) fevers due to mutations in genes encoding the pyrin superfamily.⁸⁶⁶ The gene encoding FMF, the familial Mediterranean fever (*MEFV*) gene located on chromosome 16p13.3, encodes a protein named pyrin.¹²⁶⁵ To date, more than 70 different mutations have been reported. It acts on pathways

Table 8.3 Periodic fever syndromes (autoinflammatory diseases)							
	OMIM	Gene	Inheritance	Gene location	Gene product	Major clinical features (all with fever)	Pathology
Familial Mediterranean fever (FMR)	249100	<i>MEFV</i>	AR	16p13.3	Pyrin	Erysipelas-like erythema, serosal inflammation, renal amyloidosis	Mild neutrophilic dermatosis, some perivascular accentuation, leukocytoclasia
Neonatal-onset multisystem inflammatory disorder NOMID (CINCA) CAPS	607115	<i>CIAS1</i>	AD sporadic	1q44	Cryopyrin	Urticaria, arthropathy, aseptic meningitis Some negative for mutation	Vascular dilation, urticaria, endothelial swelling, neutrophil margination, perieccrine and interstitial neutrophils NUD
Muckle–Wells syndrome CAPS	191900	<i>CIAS1</i>	AD	1q44	Cryopyrin	Urticaria, deafness, amyloidosis	Vascular dilation, urticaria, endothelial swelling, neutrophil margination and interstitial neutrophils NUD
Familial cold autoinflammatory syndrome (FCAS) CAPS	120100	<i>CIAS1</i>	AD	1q44	Cryopyrin	Cold-induced urticaria, conjunctivitis, arthralgia	Vascular dilation, urticaria, endothelial swelling, neutrophil margination and interstitial neutrophils NUD
Tumor necrosis factor receptor-associated periodic syndrome (TRAPS)	142680	<i>TNFRSF1A</i>	AD sporadic	12p13.3	TNF receptor	Migratory erythema, urticarial plaques, myalgia, pleurisy, abdominal pain	Tight perivascular lymphocytic infiltrate, ‘lymphocytic vasculitis’ – no fibrin
Pyogenic arthritis, pyoderma gangrenosum, acne (PAPA)	604416	<i>PSTPIP</i>	AD	15q24–q25.1	CD2BP1 (binds pyrin)	Acne, sterile arthritis, pyoderma gangrenosum	Severe acne, pyoderma gangrenosum
Hyperimmunoglobulinemia D syndrome (HIDS) MKD	260920	<i>MVK</i>	AR	12q24	Mevalonate kinase	Hyperimmunoglobulin D, arthralgia, abdominal pain	Acute vasculitis, may mimic EED or Sweet’s syndrome NUD
Majeed syndrome	609628	<i>LPIN2</i>	AR	18p	Unknown	Recurrent multifocal osteomyelitis, congenital dyserythropoietic anemia, Sweet’s syndrome-like lesions	Sweet’s syndrome-like No amyloid

AD, autosomal dominant; AR, autosomal recessive; CAPS, cryopyrin-associated periodic syndrome; CINCA, chronic infantile neurological, cutaneous, and articular syndrome; EED, erythema elevatum diutinum; MKD, mevalonate kinase deficiency syndrome; NUD, neutrophilic urticarial dermatosis.

involving caspase-1 and IL-1 β , leading to an increase in levels of IL-1 β . It probably enhances apoptosis.¹²⁶⁶ No mutation in the *MEFV* gene is found in some cases.

Traditionally, there are two phenotypes of FMF: type 1 manifests as recurrent short attacks of fever, inflammation, and serositis, with renal amyloidosis as the most severe complication; in type 2, asymptomatic patients present with amyloidosis as the first clinical manifestation.¹²⁶⁷ Two additional phenotypes have been described: type 3, the ‘silent’ type, in which two *MEFV* mutations are found but without signs or symptoms of FMF or amyloidosis, and an additional type seen among heterozygotes, in which there is a mild or incomplete form of the disease.¹²⁶⁸

It is most common among ethnic groups living around the Mediterranean basin and in patients with Mediterranean ancestry.¹²⁶⁵ The most serious complication of the disease is renal amyloidosis due to the deposition of serum amyloid A protein.¹²⁶⁶ IgA nephropathy is

sometimes present.¹²⁶⁹ Although 90% of patients experience their first attack before the age of 20 years, late onset has been recorded.¹²⁷⁰ The frequency of attacks may increase if isotretinoin is used to treat any concurrent acne vulgaris.¹²⁷¹

Ankylosing spondylitis and spondyloarthritis have a high prevalence among Turkish patients with FMF; these individuals are not positive for HLA-B27.¹²⁷² An occasional patient with relapsing polychondritis has been shown to be a heterozygote for FMF.¹²⁷³

Most patients are treated with colchicine, which gives a 95% response. Anakinra, the recombinant IL-1 receptor antagonist, can be used for cases not responding to colchicine.

Histopathology

There is some variability among descriptions of the microscopic findings. Generally, there is a dermal infiltrate consisting predominantly

of neutrophils. It resembles a mild neutrophilic dermatosis, but there is some perivascular accentuation. Leukocytoclasia is common. In one description of the biopsy findings from an area of erysipelas-like erythema, the changes were those of a leukocytoclastic vasculitis; direct immunofluorescence studies were negative.¹²⁷⁴ In contrast, another case showed perivascular eosinophils, neutrophils, and mononuclear cells with extravasated erythrocytes in the superficial dermis, deeper dermal edema with a sparse lymphocytic infiltrate, and a predominantly lobular panniculitis with mixed cellularity. On direct immunofluorescence, vascular deposits of C3, fibrin, and (scant) IgM were found, primarily in papillary dermal vessels.¹²⁷⁵ Vasculitides such as Henoch–Schönlein purpura and polyarteritis nodosa are more frequent in patients with FMF.^{971,1276}

AMICROBIAL PUSTULOSIS OF THE FOLDS

Amicrobial pustulosis of the folds is a relapsing, aseptic pyoderma involving predominantly the cutaneous folds and the scalp. It is often associated with autoimmune diseases such as lupus erythematosus and with ulcerative colitis or immunological abnormalities.¹²⁷⁷ It has also been associated with the rare syndrome that occurs in some patients on dapsone therapy (dapsone syndrome).¹²⁷⁷ It is mentioned in Chapter 18 because, like acrodermatitis enteropathica, it may be responsive to zinc therapy.

Histopathology

Like some other neutrophilic dermatoses, it may combine epidermal neutrophils with dermal neutrophils. The epidermal neutrophils may occur as subcorneal pustules or as neutrophilic spongiosis. The dermal neutrophils show some perivascular and perifollicular accentuation but no vasculitis. There is an admixture of other cell types such as lymphocytes, eosinophils, and a few plasma cells.¹²⁷⁷

SWEET'S SYNDROME

Sweet's syndrome (acute febrile neutrophilic dermatosis) is a rare dermatosis. It is characterized by the abrupt onset of tender or painful erythematous plaques and nodules on the face^{1278–1280} and extremities and, less commonly, on the trunk, in association with fever, malaise, and a neutrophil leukocytosis.^{1281,1282} Despite the alternative name, a fever is not always present.^{1283,1284} A variant with raised annular lesions and another with palmoplantar pustulosis have been reported.^{1285,1286} The skin lesions are sometimes studded with small vesicles or pustules, but ulceration is unusual and true bullae are uncommon.¹²⁸⁷ Facial lesions may mimic rosacea fulminans.¹²⁸⁸ A periorbital cellulitis-like lesion was the presentation in a patient with myelodysplastic syndrome.¹²⁸⁹ In another patient, the cellulitis was associated with an infiltrate of leukemic cells.¹²⁹⁰ Lesions usually heal without scarring, although there may be residual pigmentation attributed to hemosiderin. In one case, wrinkled, slack skin developed on the face following Sweet's syndrome.¹²⁹¹ There is a predilection for females; patients may be of any age, but it is rare in childhood.^{1292–1296} Familial cases have been described.¹²⁹⁷ Other clinical features may include polyarthritides, subungual erythema,¹²⁹⁸ polyneuropathy, conjunctivitis, and episcleritis.^{1282,1299,1300} Intestinal and pulmonary involvement and also neurological manifestations have been reported.^{1301–1304} An elevated C-reactive protein and erythrocyte sedimentation rate are almost invariably present.¹²⁸³

In 10–15% of cases, an associated leukemia,¹³⁰⁵ usually of acute myelomonocytic type, is present or develops later.^{1306–1316} Hairy cell leukemia developed in one case.¹³¹⁷ In some of these cases, features of atypical pyoderma gangrenosum may be present, and it has been suggested that Sweet's syndrome and pyoderma gangrenosum may be at

opposite ends of the spectrum of one process.^{1318–1322} Both Sweet's syndrome and pyoderma gangrenosum have resulted from the use of leukocyte colony-stimulating factors.^{1283,1323–1327} Concurrent Sweet's syndrome and leukemia cutis may occur in patients with myeloid disorders.¹³²⁸ Other associations have included hemophagocytic syndrome,¹³²⁹ polycythemia vera,^{1330–1333} chemotherapy-induced granulocytopenia,^{1320,1334} lymphoma,^{1335–1338} myeloma,^{1339,1340} solid cancers,^{1282,1341–1346} radiotherapy for pharyngeal carcinoma,¹³⁴⁷ a radiation field,¹³⁴⁸ splenic irradiation,¹³⁴⁹ relapsing polychondritis,^{1350–1352} Behçet's syndrome,^{1353,1354} SAPHO syndrome,¹³⁵⁵ pregnancy,^{1279,1356,1357} sarcoidosis,¹³⁵⁸ rheumatoid arthritis, lupus erythematosus,^{1359,1360} Still's disease,¹³⁶¹ pemphigus vulgaris,¹³⁶² granuloma annulare,¹³⁶³ ulcerative colitis,^{1281,1364} Crohn's disease,¹³⁶⁵ sensorineural hearing loss,¹³⁶⁶ a prothrombin gene mutation,¹³⁶⁷ subacute thyroiditis,¹³⁶⁸ erythema nodosum,^{1369,1370} cellulitis,¹³⁷¹ chronic granulomatous disease,¹³⁷² and T-cell immunodeficiency.¹³⁷³ It has been associated with infections such as chlamydial,¹³⁷⁴ dermatophytic,¹³⁷⁵ *Salmonella enteritidis*,¹³⁷⁶ *Francisella tularensis*,¹³⁷⁷ *Penicillium* species,¹³⁷⁸ *Capnocytophaga canimorsus*,¹³⁷⁹ *Helicobacter pylori*,¹³⁸⁰ staphylococcal,¹³⁸¹ streptococcal, enterococcal,¹³⁸² mycobacterial,^{1378,1383–1386} anaplasmosis (formerly ehrlichiosis),¹³⁸⁷ pulmonary coccidioidomycosis,¹³⁸⁸ hepatitis B,¹³⁸⁹ cytomegalovirus,¹³⁹⁰ herpes simplex,¹³⁹¹ rotavirus,¹³⁹² and HIV.^{1393–1395} It may follow BCG vaccination,^{1396,1397} influenza vaccination,¹³⁹⁸ pneumococcal vaccination,¹³⁹⁹ IL-2 therapy,¹⁴⁰⁰ IFN- β -1b,¹⁴⁰¹ azacitidine,¹⁴⁰² pegfilgrastim (G-CSF),¹⁴⁰³ the infusion of mitoxantrone,¹⁴⁰⁴ and the ingestion of carbamazepine,¹⁴⁰⁵ pegfilgrastim,¹³²⁷ furosemide (frusemide),¹⁴⁰⁶ minocycline,^{1407,1408} trimethoprim-sulfamethoxazole,¹⁴⁰⁹ diclofenac,¹⁴⁰⁵ aceclofenac,¹⁴¹⁰ hydralazine,¹⁴¹¹ diazepam,¹⁴¹² pegylated IFN- α in association with ribavirin,¹⁴¹³ nilotinib,¹⁴¹⁴ imatinib,¹⁴¹⁵ rofecoxib,¹⁴¹⁶ celecoxib,¹⁴¹⁷ abacavir,¹⁴¹⁸ piperacillin/tazobactam,¹⁴¹⁹ the oral contraceptive pill,¹⁴²⁰ ciprofloxacin,¹⁴²¹ adalimumab (used as therapy for refractory relapsing polychondritis),¹⁴²² bortezomib,¹⁴²³ and azathioprine.¹⁴²⁴

Photoinduced Sweet's syndrome has been reported.^{1425,1426} Bullous Sweet's syndrome has developed in an HIV-infected patient following influenza vaccination.¹⁴²⁷ Several cases have arisen in an area of post-mastectomy lymphedema.¹⁴²⁸ A Sweet's syndrome-like eruption has on each occasion followed the use of a radiocontrast agent.¹⁴²⁹ No mention was made as to whether the lesions were fixed or not.¹⁴²⁹

A case of Sweet's syndrome with a clonal neutrophilic dermatosis has been reported in a patient with CD34⁺ acute myelogenous leukemia treated with granulocyte colony-stimulating factor.¹⁴³⁰ No comment was made about the clonality of the infiltrate in another case.¹⁴³¹

The etiology is unknown, but the syndrome is assumed to represent an immunological hypersensitivity reaction triggered by some antecedent process. Sometimes there is a history of a preceding upper respiratory tract infection. Enhanced chemotaxis for neutrophils has been reported in several cases.^{1432–1434} Serum G-CSF levels are elevated in active disease.¹⁴³⁵ One study concluded that the pathogenesis is mediated through helper T-cell type 1 cytokines (IL-2 and IFN- γ).¹⁴³⁶ ANCA have also been found.¹⁴³⁷ Magro and colleagues described clonal restriction of neutrophils in 81% of cases ($n = 16$) with Sweet's syndrome and/or pyoderma gangrenosum.¹⁴³⁸ They speculated that this might be a localized form of cutaneous neutrophilic dyscrasia.¹⁴³⁸

Without therapeutic intervention, lesions may persist for weeks or several months.¹⁴³⁹ Spontaneous resolution in the first few months is uncommon.¹²⁸³ Most cases respond to oral corticosteroids.^{1283,1371,1439} In refractory cases, intravenous pulse corticosteroid has been used. Localized disease can be treated with high-potency topical corticosteroids or intralesional injections.¹⁴³⁹ Other treatments that have been used include potassium iodide and colchicine,¹⁴⁴⁰ thalidomide,¹⁴⁴¹ intravenous immunoglobulin (in a child with concurrent immunodeficiency),¹²⁹⁵ the pyrimidine analogue 5-azacytidine in a patient with myelodysplastic syndrome,¹⁴⁴² dapsone with or without corticosteroids,^{1443,1444} and the anti-IL-1 receptor antagonist anakinra.¹⁴⁴⁵

Figure 8.20 (A) Sweet's syndrome. (B) There are numerous neutrophils surrounding a dermal blood vessel that is devoid of fibrin in its wall. (H&E)

Histopathology^{1282,1446}

There is a dense infiltrate of mature neutrophils in the upper half of the dermis. Neutrophils may extend throughout the dermis and even into the subcutis. Rarely, the infiltrate is based in the deep dermis and subcutis.¹⁴⁴² Infiltrates in the subcutis are more common in patients with an underlying malignancy.¹³⁷⁸ The epidermis is usually spared, although it may be pale staining. Neutrophils may be so dense in the center of the lesion that the appearances simulate an incipient abscess. A neutrophil-poor variant is rare.¹⁴⁴⁷ Leukocytoclasia with the formation of nuclear dust is usually present, but there is usually no vasculitis or fibrinoid extravasation (Fig. 8.20). However, the vessels often show endothelial swelling. A vasculitis was seen in nearly 30% of cases in one study¹⁴⁴⁸ and in 74% of cases ($n = 31$) in another study.¹⁴⁴⁹ It was present in lesions of longer duration in one study, suggesting that it is not a primary, immune-mediated process but rather secondary to 'noxious products' released from neutrophils.¹⁴⁴⁸ Lymphocytes are present in older lesions but are usually perivascular and few in number. Lymphocytes were a presenting feature of Sweet's syndrome in two patients with myelodysplasia.^{1450,1451} Early forms of neutrophils, with bilobed nuclei, are often present and may be mistaken for other cell types. A few eosinophils may be present in the infiltrate. In later

lesions, macrophages containing phagocytosed neutrophils are sometimes prominent in the upper dermis.

Histiocytoid Sweet's syndrome¹⁴⁵² is the term used for the infiltration of histiocytoid-like cells in early lesions of Sweet's syndrome, a phenomenon first reported in 1991,¹⁴⁵³ although noted earlier.¹⁴⁴⁷ Although the immunoreactivity of the cells (CD15, CD43, CD45, CD68, MAC-386, HAM56, and lysozyme) is consistent with a monocytic-histiocytic profile, there is intense myeloperoxidase reactivity in most of the cells.¹⁴⁵² There is no gene fusion present, and the cells are not neoplastic but rather immature myeloid cells (neutrophil precursors).¹⁴⁵² Granulocyte maturation arrest led to a similar histiocytoid appearance in Sweet's syndrome following trimethoprim-sulfamethoxazole therapy.¹⁴⁵⁴ It has been suggested that prolonged follow-up evaluation of these cases is needed to 'corroborate this subset'.¹⁴⁵⁵ Since the earlier reports, Noreen Walsh and colleagues have reported six cases in which the common denominator was a dermal and/or subcutaneous infiltrate of histiocytoid myeloid cells in patients with new-onset cutaneous eruptions and systemic symptoms.¹⁴⁵⁶ Three cases most resembled histiocytoid Sweet's syndrome, two cases subcutaneous (histiocytoid) Sweet's syndrome, and one case an unspecified histiocytoid neutrophilic dermatosis.¹⁴⁵⁶ This paper adds support to the findings of Requena *et al.*, referred to previously.¹⁴⁵²

Varying numbers of atypical leukemic cells may be seen in the infiltrate in the rare cases of Sweet's syndrome precipitated by *trans*-retinoic acid treatment of a leukemia.^{1457,1458} There are reports of their presence in other cases of leukemia and myelodysplastic syndrome.^{1459,1460}

There is often marked edema of the papillary dermis that may lead to the appearance of subepidermal vesiculation (Fig. 8.21). Delicate strands of dermal collagen usually stretch across this pseudobullous space.¹²⁸² Dilated vessels and extravasated red blood cells may be found in this zone.

Destruction of dermal elastic tissue producing acquired cutis laxa (**Marshall's syndrome**) is a rare complication. It may be related to a coexistent deficiency of α_1 -antitrypsin that has been reported in this condition.¹⁴⁶¹ In one case, the elastophagocytosis was diagnosed several weeks before the diagnosis of Sweet's syndrome was made.¹⁴⁶²

A neutrophilic dermatosis resembling Sweet's syndrome was present in a case with different clinical features and reported as **neutrophilic figurate erythema of infancy**.¹⁴⁶³ A similar picture has been seen as a paraneoplastic phenomenon¹⁴⁶⁴ and as an idiopathic phenomenon.¹⁴⁶⁵ An exceedingly rare neutrophilic dermatosis that also includes vesiculation and erosions is **congenital erosive and vesicular dermatosis healing with reticulated supple scarring** (see p. 144).¹⁴⁶⁶ Mixed patterns with epidermal and dermal neutrophils have been seen in association with some malignancies and drugs.¹⁴⁶⁷

Differential diagnosis

Despite the frequently diagnostic image of Sweet's syndrome, several disorders can produce overlapping changes. Two leading ones are rheumatoid neutrophilic dermatosis and pyoderma gangrenosum. In addition to its disease association, *rheumatoid neutrophilic dermatosis* often shows denser, more deeply extending neutrophilic infiltrate than is typical of Sweet's syndrome, and leukocytoclasia may not be prominent. There are also examples of rheumatoid neutrophilic dermatosis overlying changes of interstitial granulomatous dermatitis. *Pyoderma gangrenosum* is obviously recognized as an ulcerative disease, but early lesions may show dermal edema and a dense neutrophilic infiltrate. However, it is more common for early lesions of pyoderma gangrenosum to show pustular folliculitis with abscess formation. The microscopic appearance of Sweet's syndrome lesions can also resemble erythema elevatum diutinum, except for the absence of fibrinoid material in the former. A case with clinical and histological overlap has been reported.¹⁴⁶⁸ In granuloma faciale, there are more eosinophils,

Figure 8.21 (A) Sweet's syndrome with marked subepidermal edema. (B) The underlying dermis contains a heavy infiltrate of neutrophils. (H&E)

even in early lesions, and there is a well-defined grenz zone. Cohen believes that some cases reported as neutrophilic panniculitis are really examples of subcutaneous Sweet's syndrome,¹⁴⁶⁹ a point confirmed by LeBoit.¹⁴⁷⁰

Pustular vasculitis of the hands

Pustular vasculitis of the hands (neutrophilic dermatosis of the dorsal hands) is an entity we described in 1995.¹⁴⁷¹ Since that time, we have seen other cases, and more than 50 have been reported in the literature.^{1472–1480} It appears to be a 'distributional variant' of Sweet's syndrome.¹⁴⁷⁸ There are also some similarities to atypical pyoderma gangrenosum of the hands. Its frequent distribution in the area supplied by the radial nerve is sometimes striking.¹⁴⁷¹

There has been a strong association with the subsequent development of myelodysplastic syndromes or leukemia in the cases reported subsequently. It has also been associated with inflammatory bowel disease, seropositive arthritis,¹⁴⁸¹ lymphoma,¹⁴⁸² streptococcal pharyngitis, and tonsillitis^{1479,1483} and also the ingestion of lenalidomide, an analogue of thalidomide used to treat agnogenic myeloid metaplasia.¹⁴⁸⁴ The purported absence of vasculitis in some subsequent cases led to the suggestion that neutrophilic dermatosis of the dorsal hands was a

better title.¹⁴⁷⁴ Late cases of the disease never show a vasculitis in the author's experience, and nor would one be expected if the course of other vasculitides is 'anything to go on'. Ayoub believes it is a variant of erythema elevatum diutinum and not Sweet's syndrome.¹⁴⁸⁵ Cases may be misdiagnosed as a local infection.^{1477,1486}

In a series of nine cases, five showed complete resolution with systemic corticosteroids, whereas four required ongoing therapy, usually dapsone.¹⁴⁷⁸ Recurrences were common in another series.¹⁴⁷⁷ Thalidomide, cyclosporine, methotrexate, and topical tacrolimus have also been used.¹⁴⁷⁸

Histopathology

There is intense papillary dermal edema and a heavy upper dermal infiltrate of neutrophils. A vasculitis is often present, but older lesions will, of course, not show this feature. The vasculitis has also been regarded as a 'secondary vasculitis', as opposed to a primary immune complex-mediated one.¹⁴⁸⁷ Ulceration, neutrophil exocytosis, trans-epidermal elimination of neutrophils, and phagocytosis of neutrophil debris can be seen in older lesions.

Neutrophilic fixed drug eruption

This term has been used for the neutrophilic lesions that developed after the ingestion of naproxen on several occasions.¹⁴⁸⁸ The mucosa was also involved. There was intense neutrophilic exocytosis resulting in intraepidermal pustule formation.¹⁴⁸⁸ There was upper dermal edema and a predominantly perivascular infiltrate of neutrophils that did not really resemble Sweet's syndrome. The lesions resembled those reported earlier by Agnew and Oliver.¹⁴⁸⁹

BOWEL-ASSOCIATED DERMATOSIS–ARTHRITIS SYNDROME

The use of intestinal bypass surgery for the treatment of morbid obesity is complicated in 10–20% of patients by an influenza-like illness with malaise, fever, polyarthritis, and the development of small pustular lesions in the skin of the upper extremities and trunk.¹⁴⁹⁰ Erythema nodosum-like lesions are sometimes present.¹⁴⁹¹ A similar clinicopathological syndrome has been reported rarely in patients with other bowel conditions,¹⁴⁹² such as ulcerative colitis, Crohn's disease, and intestinal diverticula, and following partial gastrectomy.^{1493–1495} In one case, it was associated with a defunctioning ileo-anal pouch.¹⁴⁹⁶ This has prompted the new designation used here in place of the previous term, the 'bowel bypass syndrome'. In one case, the patient presented with severe skin and systemic manifestations with lesions resembling necrotizing fasciitis.¹⁴⁹⁵ **Acute pustulosis of the legs** reported in a patient with diverticulitis is probably a distinct condition; it may be a variant of erosive pustular dermatosis of the legs (see p. 646).¹⁴⁹⁷

The deposition of immune complexes containing the bacterial antigen peptidoglycan, derived from an overgrowth of bacteria in a blind loop or abnormal segment of bowel, may be responsible for this syndrome.^{1490,1498} Cryoglobulins are also often present.¹⁴⁹⁸

Restoration of any correctable bowel flow usually cures the disease, but if this is not possible in the short term, oral corticosteroids, mycophenolate mofetil, dapsone, and cyclosporine can be used alone or in various combinations to achieve control.¹⁴⁹⁶

Histopathology

The changes resemble those of Sweet's syndrome, with subepidermal edema and a heavy infiltrate of neutrophils in the upper and mid dermis that is both perivascular and diffuse in distribution.¹⁴⁹⁴ There is variable leukocytoclasia. In older lesions, lymphocytes, eosinophils,

and macrophages containing neutrophil debris are also present. Although signs of vascular damage are usually limited to some endothelial swelling, fibrin deposition around vessels can be present. A purulent folliculitis has also been reported, but this is more common in the pustular lesions, particularly on the face, in patients with ulcerative colitis.¹⁴⁹⁹ Septal and lower dermal inflammation is present in the erythema nodosum-like lesions.¹⁴⁹¹

Immunofluorescence findings have not been consistent. Immunoglobulins and complement have been noted at the dermoepidermal junction and even in vessel walls.^{1491,1498}

RHEUMATOID NEUTROPHILIC DERMATOSIS

Rheumatoid neutrophilic dermatosis is a rare cutaneous manifestation of severe rheumatoid arthritis. It has until relatively recently received scant attention in the literature.¹⁵⁰⁰⁻¹⁵⁰⁶ Clinically, it presents with papules, plaques, nodules, and urticarial lesions overlying joints of the extremities, particularly the hands, resembling erythema elevatum diutinum.^{1500,1507} At other times, the lesions are flat, erythematous plaques, more widely distributed on the extremities and sometimes on the trunk.¹⁵⁰¹ A bullous variant sometimes occurs.¹⁵⁰⁸ It has also been reported in patients with seronegative rheumatoid arthritis.^{1509,1510}

Oral dapsone, sometimes with adjunctive topical corticosteroids, may clear the lesions.¹⁵⁰⁹ Oral corticosteroids can have a similar effect.¹⁵¹¹

Histopathology

There is a dense neutrophilic infiltrate throughout the dermis, but particularly in the upper and middle levels. There is variable leukocytoclasia. In late lesions, lymphocytes, plasma cells, and macrophages containing neutrophilic debris are also present (Fig. 8.22).¹⁵¹⁰ The author has been sent, in consultation, several cases of late-stage neutrophilic dermatosis, including this entity, in which neutrophils were relatively sparse, and macrophages with phagocytosed material were the predominant cell. They caused some confusion to the pathologist. There is no vasculitis in this condition.¹⁵¹¹ Sometimes the neutrophils collect in the papillary dermis, forming microabscesses similar to those seen in dermatitis herpetiformis.¹⁵⁰⁰ Intraepidermal spongiotic blisters containing a few neutrophils may also be present.¹⁵¹² Biopsies of bullous lesions have shown subepidermal separation, with an upper dermal neutrophilic infiltrate; direct immunofluorescence studies have been negative.^{1513,1514}

The author has seen a case with overlap features with interstitial granulomatous dermatitis (see p. 214). Fibrinoid collagen degeneration, resembling the collagen changes seen in rheumatoid nodules in a miniaturized form, has also been described.¹⁵¹¹

ACUTE GENERALIZED PUSTULOSIS

There have been several reports of the occurrence of a widespread pustular eruption following an infection or occurring as an idiopathic phenomenon.¹⁵¹⁵⁻¹⁵¹⁸ The terms 'acute generalized pustular bacterid'¹⁵¹⁵ and 'primary idiopathic cutaneous pustular vasculitis'¹⁵¹⁷ refer to the same condition. Most of these cases would now be regarded as variants of acute generalized exanthematous pustulosis (AGEP) (see p. 145).

Histopathology^{1515-1517,1519}

There is a large subcorneal or intraepidermal pustule overlying a massive perivascular and interstitial infiltrate of neutrophils in the upper and mid dermis. There is some exocytosis of neutrophils through the epidermis. Leukocytoclasia is variable. Vessel walls may show 'fibrinoid necrosis'. In older lesions, there are perivascular collections of lymphocytes and some eosinophils in addition to the neutrophils.

Figure 8.22 Rheumatoid neutrophilic dermatosis. A late lesion is shown. Macrophages have neutrophil debris in their cytoplasm. (H&E)

BEHÇET'S DISEASE

There are so many different manifestations of Behçet's disease that it defies most classification systems. A neutrophilic dermatosis is seen in pathergic lesions and some other stages of the disease, which is the reason for its inclusion in this section.

Behçet's disease (OMIM 109650) is a multisystem disorder in which the presence of recurrent aphthous ulcers in the oral cavity is an almost universal feature.¹⁵²⁰⁻¹⁵²² The ulcers are painful, measure 2–10 mm in diameter, and heal within 7–14 days, only to recur subsequently.^{1523,1524} Other characteristic signs include genital ulceration; ocular abnormalities such as uveitis, hypopyon, and iridocyclitis; and cutaneous lesions.¹⁵²⁵ Genital aphthae are more common in females.¹⁵²⁶ They often heal with scarring.¹⁵²⁷ Complex aphthosis (oral and genital aphthae) in the absence of other features is probably a forme fruste of Behçet's disease.¹⁵²⁸⁻¹⁵³⁰ Less frequent manifestations include synovitis, neurological lesions including meningoencephalitis, and epididymitis.¹⁵²⁵ A study from Turkey in 2007 gives some indication of the relative frequency of these various clinical features. Oral ulcers were found in all 661 patients studied. They were followed, in frequency,

by genital ulcers (85%), papulopustular lesions (55%), erythema nodosum (44%), skin pathergy (38%), and articular (33%) and ocular involvement.¹⁵³¹ The clinical course is variable; death may result from central nervous system involvement or arterial aneurysms.¹⁵³²

The most characteristic cutaneous lesions are erythema nodosum-like nodules on the legs,¹⁵³³ superficial and/or deep thrombophlebitis, acral purpuric papulonodular lesions,¹⁵³⁴ and papulopustular lesions.^{1520,1535–1537} In a study of 2319 patients in Turkey, 14.3% of patients had vascular lesions. It was the presenting sign in 2.1% of patients. More than half of all patients with vascular involvement had superficial vein thrombophlebitis, and nearly 30% had deep vein thrombophlebitis.¹⁵³⁸ Arterial lesions were rare.¹⁵³⁸ Leg ulcers are an uncommon manifestation of the disease.¹⁵³⁹ Verrucous hyperkeratotic plaques are rarely present.¹⁵⁴⁰

The development of self-healing, sterile pustules at sites of trauma ('pathergy')¹⁵⁴¹ is another characteristic feature. Pathergic lesions, which may be induced by a needle prick, are commonly seen in cases reported from Turkey but are less common in the United Kingdom.¹⁵⁴² The site most frequently positive for a pathergy reaction is the forearm, whereas the least frequent is the abdomen.¹⁵⁴³ A variant technique for demonstrating pathergy is known as the 'skin prick test with self-saliva'. Nine of 10 Behçet's disease patients developed an indurated erythema with this technique, whereas among controls, only patients with rheumatoid arthritis produced weak erythema.¹⁵⁴⁴ Lesions resembling those seen in Sweet's syndrome have also been a presenting feature.^{1545,1546}

Behçet's disease occurs most often in young adult males.¹⁵⁴⁷ It is uncommon in children.^{1548,1549} Late onset is rare,¹⁵⁵⁰ but its course in these patients is not always indolent as once thought.¹⁵⁵¹ There are different prevalence rates in different geographical areas: the highest incidence has been reported in Japan, Korea, China, and eastern Mediterranean countries.¹⁵⁵² Its prevalence in Turkey (42/10,000) is the highest in the world.¹⁵⁵³ A strong association with certain HLA types, particularly Bw51 and B12, has been reported.^{1525,1554} Meta-analyses show that HLA-B51/B5 predominates in males and is associated with higher prevalences of genital ulcers and ocular and cutaneous lesions and a decreased prevalence of gastrointestinal involvement.¹⁵⁵⁵ In Korean patients, a C438T polymorphism in the small ubiquitin-like modifier 4 (*SUMO4*) gene correlates with an increased risk of papulopustular lesions in HLA-B51+ patients.¹⁵⁵⁶ Modifications in the cytotoxic T-lymphocyte-associated antigen gene (*CTLA-4*) have been found in Behçet's disease. It appears to be a disease-modifying factor rather than a susceptibility gene because patients with certain modifications have a higher incidence of ocular and erythema nodosum-like lesions.¹⁵⁵⁷ Another study found that genetic damage (as measured by the micronucleus frequency) may play a secondary role in the etiology.¹⁵⁵⁸ Cytochrome P450 polymorphisms also occur.¹⁵⁵⁹ Deficiencies of this enzyme may lead to the formation of excessive reactive oxygen species.^{1476,1560} Polymorphisms in the TNF- α gene have been detected,¹⁵⁶¹ but *leptin* gene and toll-like receptor 2 polymorphisms have not been found.^{1562,1563} Familial cases occur.¹⁵⁶⁴ Juvenile onset is more likely in these familial cases.^{1565–1567} The frequency of severe organ involvement is higher in patients with juvenile-onset disease.¹⁵⁶⁷

There are isolated reports of hematological, lymphoid, and solid malignancies in this disease. It may not be a statistically significant increase.¹⁵⁶⁸ It has also been associated in one report with hidradenitis suppurativa (acne inversa).¹⁵⁶⁹

Numerous causes have been proposed and may be grouped into viral, bacterial, immunological, and environmental.^{1525,1552,1570–1572} An anecdotal report of its association with parvovirus B19 has been published.¹⁵⁷³ An immunological basis is most favored because of the wide variety of immunological disturbances that have been identified.¹⁵⁷⁴ These include the presence of circulating immune complexes,^{1575,1576} enhanced chemotactic activity of neutrophils,¹⁵⁷⁵ alteration of T-cell subsets,¹⁵⁷⁷ lymphocytotoxicity to oral epithelial cells or dermal micro-

vascular endothelial cells,¹⁵⁷⁸ and evidence of delayed hypersensitivity to certain streptococcal antigens.¹⁵⁷⁹ It appears to be a Th1-driven disease.¹⁵⁶¹ The common denominator in all systems appears to be a vasculitis with early infiltration by mononuclear cells and the later presence of neutrophils in some sites.¹⁵⁸⁰ The etiopathogenic role of endothelial cells is supported by the finding of increased caspase-9 expression (one initiator of apoptosis) in Behçet's disease.¹⁵⁸¹ Vascular endothelial growth factor may contribute to the formation of ocular and other lesions.^{1582,1583} An IgM-type anti-endothelial antibody has also been detected.¹⁵²² E-selectin and P-selectin are increased in endothelial cells of patients with a skin pathergy reaction.¹⁵⁸⁴ Endothelial markers were not increased in panniculitic lesions of Behçet's disease.¹⁵⁸⁵

The serum IL-8,^{1586,1587} IL-6, serum adenosine deaminase,¹⁵⁸⁸ substance P,¹⁵⁸⁹ C-reactive protein,¹⁵⁹⁰ and lipoprotein^{1591,1592} levels are a reliable marker of disease activity. Anticardiolipin antibodies are sometimes present.¹⁵⁹³ IL-23 levels are increased in the erythema nodosum-like lesions.¹⁵⁹⁴ Peripheral insulin resistance is another manifestation of the disease.¹⁵⁹⁵ Increased nitric oxide production^{1596,1597} and heat shock proteins^{1582,1598} have been reported. Nitric oxide levels were normal in one study.¹⁵⁹⁹

Reciprocal expression of matrix metalloproteinase (MMP)-2 (low) and MMP-9 (high) has been found in tissues from patients with Behçet's disease, with evidence that the MMP-9-1562*/C/*C haplotype may promote the disease.¹⁶⁰⁰ No standard treatment regimen has been established for this disease. Numerous treatments have been used, including colchicine, thalidomide, corticosteroids, chlorambucil, cyclophosphamide, cyclosporine, azathioprine, sulfasalazine, granulocyte and monocyte adsorption apheresis,¹⁶⁰¹ etanercept,¹⁶⁰² and IFN- α -2a.^{1566,1572,1603} One patient, who had tried various other therapies, responded well to lenalidomide, an analogue of thalidomide.¹⁶⁰⁴

Histopathology

In aphthous ulcers, there is a variable infiltrate of lymphocytes, macrophages, and neutrophils in the base of the ulcer (Fig. 8.23).¹⁵⁷⁷ The infiltrate is accentuated around small vessels and also extends into the epithelium at the margins of the ulcer.^{1579,1605} Some of the intraepithelial lymphocytes appear activated with large indented nuclei.¹⁶⁰⁶ Degen-erating prickles cells may be present in the marginal epithelium. There is a virtual absence of plasma cells in early lesions, but these may be quite prominent in older lesions.¹⁶⁰⁵

Figure 8.23 Behçet's syndrome. There is a mucosal ulcer with mixed dermal infiltrate, vascular proliferation, and adjacent acanthosis. (H&E)

The *erythema nodosum-like lesions* show a perivascular infiltrate of lymphocytes and other mononuclear cells in the deep dermis and the septa of the subcutaneous fat.¹⁶⁰⁷ Lymphocytes may extend into vessel walls in the manner of a lymphocytic vasculitis. Endothelial cells are often enlarged and sometimes show degenerative features, particularly on ultrastructural examination.¹⁶⁰⁷ Subsequently, neutrophils are found in the perivascular collections and in some cases are quite numerous.¹⁶⁰⁷ They are much more common than in erythema nodosum.¹⁶⁰⁸ Kim and LeBoit believe that vasculitis is an important event in the pathogenesis of the lesions.¹⁶⁰⁹ The lesions lack the histiocytic granulomas of the usual type of erythema nodosum.¹⁵²⁵ A lobular panniculitis has also been described in lesions of Behçet's disease.¹⁵³³ It closely mimics nodular vasculitis, but a neutrophil-predominating infiltrate is more common in Behçet's disease.¹⁶⁰⁸ Polyp-like structures, composed of lipophages, have been found protruding into cavities resulting from lysis of fat cells in the lobular panniculitis of Behçet's disease.¹⁶¹⁰

In *pathergic lesions*, there is a heavy neutrophil infiltrate, without fibrinoid changes, in the vessel walls. This has been called pustular vasculitis or 'Sweet's-like vasculitis' to distinguish it from leukocytoclastic vasculitis in which fibrinoid change and leukocytoclasia are prominent features.¹⁶¹¹ Intraepidermal pustules may occur at the point of impact of the pathergic stimulus (Fig. 8.24).¹⁶¹² Despite the attention given to the neutrophilic infiltration, recent detailed studies of pathergic lesions have found a significant mononuclear cell infiltrate in the dermis, around vessels and appendages, and extending into the deep dermis.¹⁶¹³ The skin prick test with self-saliva shows perivascular inflammation with a predominance of CD4⁺ lymphocytes and significant numbers of CD68⁺ monocytes/macrophages, findings consistent with a delayed hypersensitivity response.¹⁵⁴⁴

In some lesions of Behçet's disease, the pattern is that of a tight superficial and deep perivascular infiltrate of mononuclear cells. A lymphocytic or leukocytoclastic vasculitis may be present,^{1614,1615} leading to the suggestion that Behçet's disease should be set aside from the neutrophilic dermatoses and classified as a true vasculitis.¹⁶¹⁶ A leukocytoclastic vasculitis is often present in nonfollicular papulopustular lesions.^{1617,1618} Usually, a few perivascular or interstitial neutrophils will be found.¹⁵²⁰ Skin biopsy specimens are often non-specific.¹⁶¹⁹ Amyloid deposits were found within a papulopustular lesion of one case.¹⁶²⁰ Immunohistochemical analysis of the inflammatory infiltrates in Behçet's disease skin lesions has shown that CD68⁺

cells predominate in erythema nodosum, erythema multiforme-like, and Sweet's-like lesions, whereas neutrophils predominate in papulopustular lesions. In all of these types of skin lesions, there is a higher percentage of CD8⁺ than CD4⁺ cells, and IL-4 expression is stronger than IFN- γ expression.¹⁶²¹ The thrombophlebitic lesions are rarely biopsied. Folliculitis, acneiform lesions,¹⁶²² dermal abscesses, polyarteritis nodosa,¹⁶²³ and a necrotizing vasculitis⁷⁸⁹ have all been described in Behçet's disease.¹⁶²⁴

Immunofluorescence studies have shown IgM and C3 in aphthous lesions, often diffusely distributed.¹⁵⁷⁹ Immunoreactants are a less constant feature in the erythema nodosum-like lesions. Increased lesional expression of bcl-2 has been found in some cases.^{1625,1626} There is an accompanying loss of Fas (CD95) expression in dermal lymphocytes.¹⁶²⁶

Differential diagnosis

A specific microscopic determination that a lesion is due to Behçet's disease is difficult, if not impossible, in the absence of clinical information. Aphthae in patients with Behçet's disease cannot be reliably distinguished microscopically from recurrent aphthous stomatitis in those who do not have Behçet's disease. However, with direct immunofluorescence, perivascular IgM and C3 deposits are seen in perilesional tissue of Behçet's disease patients but (at least in one study) not in patients with recurrent aphthous stomatitis.^{1627,1628} The most characteristic changes occur in pathergic lesions and perhaps in those examples of erythema nodosum that also feature thrombophlebitis.¹⁶²⁹ *Pathergy* is not always demonstrable in Behçet's syndrome, while at the same time it can be seen in patients with *pyoderma gangrenosum*, *inflammatory bowel disease*, and in some forms of *leukemia*. *Superficial migratory thrombophlebitis* has other disease associations, but microscopically inflammation is confined to the immediate vicinity of the involved vessel; additional changes of erythema nodosum would not be expected, and therefore this combination would favor Behçet's syndrome.

ABSCESS-FORMING NEUTROPHILIC DERMATOSIS

Some patients with hematological malignancies present with pustules and abscesses that do not clinically resemble Sweet's syndrome or pyoderma gangrenosum.¹⁴⁷⁴ This group appears to represent another type of neutrophilic dermatosis.

Histopathology

There is a dense dermal infiltrate of neutrophils with the formation of dermal abscesses. There is usually subepidermal edema. Extensive leukocytoclasia is seen in older lesions.

CHRONIC LYMPHOCYTIC VASCULITIS

Lymphocytic vasculitis is not a disease sui generis but rather a group term for a number of clinically heterogeneous diseases that on histopathological examination have evidence of a lymphocytic vasculitis; that is, there is a predominantly lymphocytic infiltrate involving and surrounding the walls of small vessels in the dermis.¹⁶³⁰ Often, there is associated endothelial cell swelling and some extravasation of erythrocytes, but nuclear dusting is uncommon. Although there may be an extravasation of fibrin into vessel walls, this feature should not be a requirement for the diagnosis of lymphocytic vasculitis. After all, exudative phenomena are not usually a feature of chronic inflammation.

The previous definition of lymphocytic vasculitis has been criticized as "failing to provide objective criteria that would enable a pathologist

Figure 8.24 Pathergy in Behçet's syndrome. A neutrophilic pustule is associated with an underlying mixed perivascular inflammatory infiltrate. (H&E)

to determine whether an infiltrate ‘involves’ a vessel rather than merely exiting through it at the time that the biopsy specimen is taken.¹⁶³¹ The phenomenon of ‘exiting’ (diapedesis) does not occur in *normal* arteries or veins, nor is it such a widespread or prominent phenomenon in smaller vessels (e.g., postcapillary venules) that it is likely to be mistaken for lymphocytic vasculitis. If the criteria are made too rigid and problems associated with sampling and evolution of the disease are not acknowledged, then lymphocytic vasculitis becomes a rare diagnosis and ‘lymphocytic perivasculitis’ and ‘perivascular dermatitides’ assume an importance they do not deserve.¹⁶³² The article referred to previously defined cutaneous lymphocytic vasculitis as requiring the presence of either acute or chronic damage to the walls of small vessels (e.g., fibrin deposition, lamination by pericytes). In the case of muscular vessels, the presence of lymphocytes within the vessel wall is sufficient, because diapedesis of lymphocytes does not occur in arteries or veins.¹⁶³¹

In the authors’ view expressed in that publication, the pigmented purpuric dermatoses did not meet these criteria, but atrophie blanche and Sneddon’s syndrome did.¹⁶³¹ Although this concept may be valid for normal veins, it does not apply to veins in which the endothelial cells have taken up antigen (virus, drugs, and bacteria), thereby specifically attracting cytotoxic T lymphocytes that cause endothelial damage and allow the diapedesis of lymphocytes (discussed later).¹⁶³³ Furthermore, the continued fixation on the requirement for fibrin to be present in every case of vasculitis has hampered the diagnosis of this condition. It ignores the basic fact that exudative phenomena (including the presence of fibrin) are not a feature of chronic inflammation in any other organ system. Why single out vasculitis and make its presence a requirement?

Kossard defined three forms of lymphocytic vasculitis: an angiodestructive form seen in association with Behçet’s disease, acute lupus erythematosus, lupus panniculitis, late stages of acute vasculitis, and in cases that may clinically mimic acute vasculitis with palpable purpura; lichenoid lymphocytic vasculitis, as defined later; and lymphocytic endovasculitis, in which there is intimal hyperplasia with vessel wall mucinosis or segmental hyalinosis and a variable lymphocytic infiltrate.¹⁶³⁴ Kossard states that these three major patterns are not mutually exclusive.¹⁶³⁴

Experimental work offers support for the concept of lymphocytic vasculitis. Dermal endothelial cells usually form a continuous lining that bars blood-borne T lymphocytes from entering the skin, but under the influence of a foreign antigen (e.g., virus or drug antigen) endothelial cells may help initiate cutaneous immune reactions by presenting these foreign antigens to circulating T-memory cells.¹⁶³³ Endothelial cells have unique expression patterns of adhesion molecules such as E-selectin, ICAM-1, and VCAM-1 that can determine the subsets of memory T cells that are recruited into the skin.¹⁶³³ Endothelial cells strongly express class I and class II major histocompatibility complex (MHC) molecules. Presumably, antigens within endothelial cells, in association with MHC class I peptides, stimulate a CD8⁺ cytotoxic reaction resulting in endothelial cell killing – a lymphocytic endothelialitis/vasculitis.¹⁶³³ In contrast, CD4⁺ T cells which recognize class II peptides produce cytokines that attract effector cells of innate immunity (neutrophils, eosinophils, and macrophages) that eradicate extracellular microbes more efficiently.¹⁶³³ This work by Pober and colleagues from Yale University provides a probable explanation for the mechanism of lymphocytic vasculitis.¹⁶³³ In this mechanism, the presence of fibrin would be an epiphenomenon – a point that the author has tried to make for decades. There are obviously other mechanisms that result in a lymphocytic vasculitis as evidenced in the setting of pigmented purpuric dermatosis, malignant atrophic papulosis, and lupus erythematosus profundus.¹⁶³⁵ Interestingly, in congenital chilblain lupus (see p. 68), the inheritance of a single abnormal protein results in an immune response leading to the formation of perniosis, a lymphocytic vasculitis.

Carlson and Chen have accepted a broader definition of lymphocytic vasculitis and accept connective tissue disease such as lupus erythematosus, endothelial infection by viruses and *Rickettsia*, as well as lichenoid diseases such as perniosis and PLEVA.⁹⁰⁵ They also include drug reactions, some arthropod assaults, Behçet’s disease, Degos disease, Sneddon’s syndrome, Kawasaki disease, and superficial thrombophlebitis.⁹⁰⁵

The following clinical conditions may be regarded as lymphocytic vasculitides:

- Inherited lymphocytic vasculitis
- Toxic erythema
- Collagen vascular disease
- PUPPP (polymorphic eruption of pregnancy)
- Prurigo of pregnancy
- Gyrate and annular erythemas
- Pityriasis lichenoides
- Pigmented purpuric dermatoses
- Malignant atrophic papulosis (Degos)
- Perniosis
- Rickettsial and viral infections
- Pyoderma gangrenosum
- Polymorphic light eruption (one variant)
- TRAPS
- Leukemic vasculitis.

Sneddon’s syndrome could also be included, but it was discussed previously in this chapter (see p. 226). Note that the inclusion of several of these entities is controversial; this is considered further in the discussion that follows. A lymphocytic vasculitis has also been reported in the toxic shock syndrome, which results from a toxin produced by *S. aureus*,¹⁶³⁶ but it is not an invariable finding in this condition. Some drugs, such as aspirin, acetaminophen (paracetamol, Panadol®), lipid-lowering agents, and herbal medicines, may give this pattern. A localized lymphocytic vasculitis has been reported at the site of injection of etanercept.¹⁶³⁷ A thrombotic lymphocytic vasculitis has followed the use of IVIG.¹⁶³⁸ It was a generalized reaction. It may also occur in connective tissue diseases. Behçet’s syndrome can also be included as a lymphocytic vasculitis. The condition known as lymphocytic thrombophilic arteritis, previously reported as macular arteritis, is an arteritis of medium-sized vessels. The infiltrate is predominantly lymphocytic, but there are a few neutrophils and eosinophils together with nuclear dust. It is mentioned further in the section on polyarteritis nodosa (see p. 244).^{1172,1173}

Lymphocytic vasculitis is a rare manifestation of leukemia.¹⁶³⁹ More common is leukemic vasculitis, a manifestation of leukemia cutis in which atypical blast cells, rather than inflammatory cells, infiltrate vessel walls. A recently reported patient receiving etanercept for treatment of a chronic lymphocytic vasculitis developed acute myeloid leukemia with specific cutaneous infiltrates.¹⁶⁴⁰ Some atypical lymphoid cells were seen in the lymphocytic vasculitis with associated epidermotropism that appeared as a localized reaction, following the application of imiquimod for the treatment of basal cell carcinoma.¹⁶⁴¹

Lichenoid lymphocytic vasculitis (Fig. 8.25) is a specific variant of lymphocytic vasculitis, characterized by the additional feature of a lichenoid tissue reaction (interface dermatitis), often mild. It is seen as a disordered cellular immune reaction to some viruses and putative viruses and in some drug reactions. Pityriasis lichenoides, some cases of erythema multiforme, and variants of Gianotti–Crosti syndrome may have this histological pattern. Combinations of an interface dermatitis, several patterns of vasculitis, and a diffuse histiocytic infiltrate have been reported by Magro and Crowson as a superantigen id reaction associated with various microbial pathogens.¹⁶⁴² The author does not recall ever seeing such a pattern.

Figure 8.25 (A) Lichenoid lymphocytic vasculitis. (B) There are prominent interface changes. This patient had a persistent dermatosis following a viral-like illness. It did not resemble any named dermatosis. (H&E)

INHERITED LYMPHOCYTIC VASCULITIS

A large, multigenerational family has been reported with a symmetrical, cutaneous small vessel lymphocytic vasculitis involving the cheeks, thighs, and hands (OMIM 609817).¹⁶⁴³ It was inherited as an autosomal dominant trait with incomplete gene penetrance. The responsible gene was mapped to a region on chromosome 6q26–q27, but no mutations could be found in the two genes that reside in this area, *CCR6* and *GPR31*.¹⁶⁴³ Histological examination showed a lymphocytic vasculitis with red cell extravasation.¹⁶⁴³

TOXIC ERYTHEMA

Toxic erythema is a poorly defined clinical entity in which there is a macular or blotchy erythema, sometimes with a small purpuric component. It is usually present on the trunk and proximal extremities. The histopathological term 'lymphocytic vasculitis' is sometimes given clinical connotations and used in place of toxic erythema: this should be avoided because the histological picture that this term describes is common to several clinically distinct conditions.

Toxic erythema may result from the ingestion of various drugs, including antibiotics, oral contraceptives,¹⁶⁴⁴ aspirin, and, rarely, acetaminophen (paracetamol), as well as various preservatives and dyes added to foods.¹⁶⁴⁵ Viral infections are sometimes implicated. Often,

Figure 8.26 Toxic erythema with a lymphocytic vasculitis. There is no fibrin in vessel walls. Fibrin is often absent in the lymphocytic vasculitides. (H&E)

the etiology of toxic erythema is unknown or at best presumptive. Toxic erythema of chemotherapy is a different condition, in which the principal histopathologic features consist of epidermal and sweat duct dysmaturation and vacuolar alteration of the epidermal basilar layer. Eccrine hidradenitis has been reported, but in other respects dermal infiltrates are either not mentioned or described as sparse. In one report of a case of toxic erythema due to gemcitabine and docetaxel, a perivascular infiltrate composed of lymphocytes, histiocytes, and eosinophils was described.¹⁶⁴⁶ Lymphocytic vasculitis is not a feature in this form of toxic erythema.¹⁶⁴⁷

Histopathology

The appearances are those of a lymphocytic vasculitis, as described previously (Fig. 8.26). A small amount of nuclear dust is sometimes present, although fibrin extravasation is quite uncommon.

COLLAGEN VASCULAR DISEASE

The term 'collagen vascular disease' is still widely used for a group of related diseases in which the skin, soft tissues, muscles, joints, and various other organs may be involved. Sometimes, the clinical features do not fulfill the criteria for the diagnosis of a named disease such as lupus erythematosus, rheumatoid arthritis, or dermatomyositis. Cutaneous manifestations are variable and may be intermittent. There may be widespread erythematous lesions resembling toxic erythema (see above). In their early stages, some connective tissue diseases are 'undifferentiated' and not specific for a particular disease subset. Such cases may present as a lymphocytic vasculitis.¹⁶⁴⁸

Histopathology

There is a lymphocytic vasculitis that usually involves both the superficial and deep plexuses (Fig. 8.27). There is sometimes mild fibrin extravasation in scattered vessels. In recurrent lesions and those of long duration, mild thickening of the walls of venules and capillaries, indicative of previous fibrin extravasation, may be seen.

PRURITIC URTICARIAL PAPULES AND PLAQUES OF PREGNANCY (PUPPP)

PUPPP,^{1649–1656} which occurs in approximately 1 in 200 pregnancies, has other synonyms, such as toxic erythema of pregnancy¹⁶⁵⁷ and

Figure 8.27 Collagen vascular disease. The patient had arthralgia, mild muscle weakness, and an erythematous maculopapular eruption. (H&E)

late-onset prurigo of pregnancy.^{1658,1659} PUPPP is the usual designation in the United States, whereas PEP (polymorphic (polymorphous) eruption of pregnancy) is used in Europe and the United Kingdom.^{1660–1662} It presents as an intensely pruritic eruption of papules and urticarial plaques, sometimes studded with small vesicles. Targetoid lesions have been described.¹⁶⁶³ The lesions develop in and around the abdominal striae in the last few weeks of pregnancy.^{1664,1665} Subsequently, they may become widespread on the trunk and limbs, but in contrast to pemphigoid gestationis (herpes gestationis), there is usually sparing of the periumbilical region.¹⁶⁵⁷ Involvement of the whole skin, including the face, palms, and soles, is rarely seen,¹⁶⁶⁶ although a postpartum case involving the palms and soles has been reported.¹⁶⁶⁷ The rash usually resolves spontaneously or with delivery.¹⁶⁶⁸ A recent case persisted until 10 weeks postpartum.¹⁶⁶⁹ Approximately 15% of cases commence in the immediate postpartum period.^{1666,1670} There are no adverse effects on fetal outcome.¹⁶⁷¹ Only occasionally does it recur in subsequent pregnancies.¹⁶⁵¹ Recurrence of similar lesions much later in life has been reported in one patient.¹⁶⁷² The finding of increased maternal weight gain,¹⁶⁶⁶ increased neonatal birth weight (not always), and increased twin and triplet rate suggests that abdominal distension or a reaction

to it may play a role in the development of this condition.^{1666,1673–1680} A study from Paris confirmed the already accepted association with male fetuses and multiple gestation pregnancies.¹⁶⁶⁵ The occurrence of familial cases (in which sisters were married to brothers of another family) raises the possibility of a paternal influence such as a circulating paternal factor.¹⁶⁸¹

One large study gives some perspective to the relative incidence of the various pruritic lesions of pregnancy.¹⁶⁸² Fifty-one cases were identified in 3192 pregnancies. Of these, 2 cases were herpes gestationis, 17 were pruritus gravidarum (pruritus with normal skin, apart from excoriations), 15 were PUPPP, 7 were prurigo of pregnancy (of Besnier), 1 was pruritic folliculitis of pregnancy, 2 were intercurrent disease (scabies and exfoliative dermatitis), and 7 were not diagnosed.¹⁶⁸² A recent study of 401 patients with specific dermatoses of pregnancy found that 49.7% had eczema in pregnancy, 21.6% had polymorphic eruption of pregnancy, and 4.2% had pemphigoid gestationis.¹⁶⁸³ Only occasional cases of pruritic folliculitis of pregnancy and prurigo of pregnancy were diagnosed, and these cases showed considerable overlap with eczematous cases and were summarized as atopic eruption of pregnancy.¹⁶⁸³ This study has been criticized subsequently because of its overemphasis on eczema and the use of soft criteria for the diagnosis of atopy.¹⁶⁸⁴

Topical treatment with corticosteroids and emollients is usually sufficient to control symptoms in the majority of patients.¹⁶⁶⁶ Systemic antihistamines are often used.¹⁶⁸⁵ In occasional cases, oral prednisolone is used because of extensive lesions or the lack of response to topical agents. Their use in the late stages of pregnancy does not seem to have any adverse effects.¹⁶⁸⁵

Histopathology¹⁶⁵⁷

There is a lymphocytic vasculitis with a varying admixture of eosinophils and variable edema of the papillary dermis.¹⁶⁵⁹ The infiltrate may only involve the superficial plexus, although at other times it extends to a deeper level. A variant with interstitial eosinophils, resembling an arthropod bite reaction, is sometimes seen. However, this variant differs from a bite reaction by the absence of a wedge-shaped infiltrate and no deep extension of the infiltrate. There is sometimes perivascular edema in the dermis. Nuclear dust has been present in a few cases,¹⁶⁸⁶ but there is no fibrin extravasation. Epidermal changes are present in approximately one-third of cases and include focal spongiosis and parakeratosis (Fig. 8.28).¹⁶⁸⁷ Small spongiotic vesicles may be present in older lesions. Exocytosis of inflammatory cells is sometimes present.

Immunofluorescence studies are usually negative, in contrast to the finding of C3 in the basement membrane zone in pemphigoid gestationis.¹⁶⁴⁹ However, nonspecific immunoreactants may be found in dermal blood vessels and near the dermoepidermal junction.^{1666,1688} A possible subset, with circulating IgM antibodies to the basement membrane zone, has been suggested;¹⁶⁸⁹ a subsequent study has shown that normal pregnancy may be associated with low levels of IgM autoreactivity against epidermal proteins.¹⁶⁹⁰

Differential diagnosis

The most significant differential diagnostic consideration is *pemphigoid gestationis*, which tends to occur late in pregnancy. This condition can present with urticarial lesions and is quite pruritic. However, pemphigoid gestationis begins during the second trimester, often presents with bullae (vesicles may occur in PEP, but these are small and form on the basis of spongiosis), may continue following delivery (the author has seen pemphigoid gestationis continue for up to 1 year following parturition), and recurs with succeeding pregnancies.

Typically, papillary dermal edema and subepidermal blister formation, along with the spongiosis, also occur. Direct immunofluorescence studies are particularly helpful in this situation because pemphigoid

Figure 8.28 (A) PUPPP. (B) Focal spongiosis overlies a lymphocytic vasculitis. (H&E)

gestationis shows linear C3 and, sometimes, IgG deposition at the dermal–epidermal junction, whereas the immunofluorescence changes in PEP are negative or nonspecific.

PRURIGO OF PREGNANCY

The term ‘prurigo of pregnancy’ has been proposed for another pruritic eruption of pregnancy characterized by widely scattered acral papules, usually arising earlier in pregnancy than PUPPP.^{1691–1693} Some papules may also be present on the abdomen.¹⁶⁹⁴ The onset in one study was at 22 (± 9) weeks of gestation.¹⁶⁸² It usually resolves after delivery, but it may persist for months postpartum.¹⁶⁶¹ It has no effect on the pregnancy. It is possibly a heterogeneous entity that includes prurigo gestationis of Besnier, early onset prurigo of Nurse,¹⁶⁵⁸ pruritic papules of pregnancy,¹⁶⁹⁵ and papular dermatitis of pregnancy.¹⁶⁸⁷ A variant termed prurigo pigmentosa has also occurred during pregnancy; this condition combines pruritic plaques and vesicles with reticulate hyperpigmentation.¹⁶⁹⁶ It has been suggested that many cases of prurigo of pregnancy may in fact have been cases of ‘eczema’, which appears to be increased in pregnancy.¹⁶⁷¹ This was confirmed in a later study.¹⁶⁸³

Treatment is with moderately potent topical corticosteroids. Other antipruritic agents, such as the antihistamine chlorpheniramine, may also be used.¹⁶⁶¹

Histopathology

There are few descriptions of the histopathological changes. A lymphocytic vasculitis similar to that of toxic erythema of pregnancy is present, with the additional features of focal parakeratosis, acanthosis, and sometimes excoriations.^{1661,1695} In some cases, the infiltrate is only loosely arranged around vessels, and there is then no evidence of vasculitis.¹⁶⁸² Prurigo pigmentosa features basilar hypermelanosis and an extensive dermal lymphohistiocytic infiltrate with exocytosis.¹⁶⁹⁶

GYRATE AND ANNULAR ERYTHEMAS

The gyrate and annular erythemas are a heterogeneous group of dermatoses that are akin to toxic erythema¹⁶⁹⁷ in having a tight perivascular lymphohistiocytic infiltrate, which at times involves the vessel walls in the manner of a lymphocytic vasculitis. Clinically, there are one or more circinate, arcuate, or polycyclic lesions that may be fixed or migratory.^{1697–1699} The term ‘palpable migratory arciform erythema’ has

been used for the variant with arcuate lesions.¹⁷⁰⁰ An annular erythema is a rare pattern of presentation of juvenile mycosis fungoides.¹⁷⁰¹

Histopathologically, the gyrate and annular erythemas have been divided on the basis of the distribution of the perivascular infiltrate into a superficial type and a deep type.¹⁷⁰² The superficial erythemas are usually accompanied by slight spongiosis and focal parakeratosis, which corresponds to the peripheral scale noted clinically. In the deep type, there is no spongiosis or parakeratosis, and clinically the lesions have a firm cord-like border but no scale. Both types have been included within the entity known as erythema annulare centrifugum, suggesting that it is a heterogeneous entity.¹⁷⁰³ The various clinical forms of gyrate and annular erythema fall into one or other of these pathological groups.

The following conditions are considered:

- Erythema annulare centrifugum
- Erythema gyratum repens
- Erythema marginatum
- Annular erythemas of infancy
- Erythema chronicum migrans.

Erythema annulare centrifugum

Erythema annulare centrifugum is characterized by the presence of one or more annular, erythematous lesions that may spread outwards or remain stationary.^{1697,1698} A fine scale is sometimes present inside the advancing edge. The lesions may be pruritic. They are found most commonly on the trunk and proximal parts of the limbs. The peak incidence is mid-adult life, but neonatal onset has been reported.¹⁷⁰⁴

A variety of agents have been implicated in the etiology of erythema annulare centrifugum, but in a significant number of cases no etiological agent can be found.¹⁶⁹⁸ The condition has been associated with infections by bacteria,¹⁷⁰⁵ rickettsia,¹⁷⁰⁶ viruses,¹⁷⁰⁷ including HIV infection,¹⁷⁰⁸ and fungi, and also with infestation by parasites,¹⁷⁰⁹ including generalized *Phthirus pubis* infestation.¹⁷¹⁰ Malignant tumors,^{1711–1713} leukemia,^{1714,1715} foods,¹⁶⁹⁸ and drugs¹⁷¹⁶ have also been blamed. The drugs have included penicillin, cimetidine,¹⁷¹⁷ etizolam,¹⁷¹⁸ gold,¹⁷¹⁹ salicylates, thiazides,¹⁷²⁰ alendronate,¹⁷²¹ estrogen–progesterone in oil, ustekinumab,¹⁷²² and antimalarials.¹⁷²³ Erythema annulare centrifugum as a paraneoplastic phenomenon has been designated PEACE (paraneoplastic erythema annulare centrifugum eruption); it is more commonly seen in women, typically precedes the clinical diagnosis of malignancy, and may recur with subsequent relapses.¹⁷²⁴ It has developed in pregnancy, clearing after delivery.¹⁷²⁵ It has also occurred as a manifestation of autoimmune progesterone dermatitis.¹⁷²⁶ The recurrent annular erythema that is occasionally seen in patients with anti-Ro/SSA antibodies, in association with SLE or with Sjögren's syndrome, has a wide, elevated border.^{1727–1733} Other immunological associations of this variant of annular erythema have been reported.^{1734,1735}

The pathogenetic mechanism is unknown; a hypersensitivity reaction to one or other of the agents mentioned previously has been suggested.¹⁷²⁰ Annual recurrence has occurred in several patients, but no precipitating factor could be detected.¹⁷³⁶ It has followed herpes zoster, a probable manifestation of Wolf's isotopic response.^{1737,1738}

It is often a self-limiting disorder that resolves spontaneously over several weeks. However, the disease may persist for years. No single therapy has proved effective. Any possible triggering factor should be eliminated. Topical and systemic corticosteroids, PUVA therapy, calcipotriol,¹⁷³⁹ and metronidazole¹⁷⁴⁰ have all been used at some time to treat the disease.

Histopathology^{1698,1703}

As mentioned previously, two distinct patterns – a superficial type and a deep type – may be found. Because most cases of the superficial type of erythema annulare centrifugum have epidermal changes with

Figure 8.29 Erythema annulare centrifugum. (A) Superficial type. There are focal parakeratosis, irregular acanthosis with spongiosis, and a superficial perivascular lymphocytic infiltrate. The findings are quite similar to those of pityriasis rosea. (H&E) (B) Superficial and deep type. This lesion shows the characteristic 'coat-sleeved' perivascular lymphocytic infiltrate involving both superficial and deep vascular plexuses. (H&E)

pityriasiform spongiosis, this condition has also been considered in Chapter 5, page 112, along with pityriasis rosea, from which it may be histologically indistinguishable (Fig. 8.29A). In the *superficial variant*, there is also a moderately dense infiltrate of lymphocytes, histiocytes, and, rarely, eosinophils around vessels of the superficial vascular plexus. The infiltrate is well demarcated and has a 'coat-sleeve' distribution. Cells may extend into the walls of the small vessels, but there is never any fibrin extravasation. It is a pseudovasculitis rather than a vasculitis. There may be slight edema of the papillary dermis. At the advancing edge, there are pityriasiform features, as previously mentioned.

In the *deep type*, a similar infiltrate involves both superficial and deep vascular plexuses (Fig. 8.29B). The epidermis is normal, but Weyers and colleagues described occasional apoptotic keratinocytes and vacuolar change.¹⁷⁴¹ They believe that the deep form may be a manifestation of tumid lupus.

A leukocytoclastic vasculitis was present in a patient with malignant lymphoma who had an unusual purpuric type of annular erythema.¹⁷⁴²

In another patient with leukemia, an eosinophil-rich infiltrate was present in the dermis.¹⁷⁴³ A rare neutrophilic dermatosis presenting as erythema annulare centrifugum-like lesions has been described; in one case, there was a perivascular and interstitial dermal infiltrate composed mainly of neutrophils, with a few lymphocytes and eosinophils.¹⁷⁴⁴

Differential diagnosis

The microscopic findings of superficial erythema annulare centrifugum resemble not only those of pityriasis rosea but also, at times, those of other forms of spongiotic dermatitis. Often, clinical information is necessary to make the distinction. In larger biopsies, a more or less discrete focus of parakeratosis may suggest a trailing edge of scale in cross-section. Special stains (especially periodic acid–Schiff (PAS) and methenamine silver) can be obtained to exclude dermatophytosis. When fully developed, the deep form of erythema annulare centrifugum can produce a rather classic microscopic image, but earlier lesions, or those with lesser degrees of inflammation or coat-sleeving, can be difficult to distinguish from other disorders with perivascular lymphocytic infiltrates. A lack of periadnexal involvement and interstitial mucin deposition would argue against tumid lupus erythematosus/lymphocytic infiltration of Jessner. Polymorphic light eruption has overlapping features, including a similar depth of dermal perivascular inflammation, but often displays papillary dermal edema and may have epidermal changes such as spongiosis. Eosinophils are not common in erythema annulare centrifugum, and their presence may suggest reaction to arthropod. However, the author has seen at least one long-standing case of recurrent erythema annulare centrifugum that did display eosinophils in some of the specimens. Finally, dense perivascular lymphocytic infiltrates could raise the specter of angiocentric lymphoma, but lymphocyte atypia is minimal and gene rearrangement studies are negative in erythema annulare centrifugum.

Erythema gyratum repens

Erythema gyratum repens is rare and is the most distinctive of the gyrate erythemas.^{1698,1699,1745} There are broad erythematous bands arranged in an arcuate or polycyclic pattern, often accompanied by a trailing scale and likened to wood grain or marble.¹⁷⁴⁶ The eruption, which is often pruritic, may migrate up to 1 cm per day. It is usually confined to the trunk and proximal parts of the limbs; the face is not affected.¹⁶⁹⁷ The eruption has been reported to evolve from an initial erythroderma.¹⁷⁴⁷

Erythema gyratum repens is usually associated with an internal cancer, particularly of pulmonary origin.^{1748,1749} It has been reported in association with transitional cell carcinoma of the kidney and acquired ichthyosis.¹⁷⁵⁰ However, it is not regarded as an obligate paraneoplastic disease. Thus, in one review of 112 cases reported in the literature, 30% of 83 cases accepted as true examples of erythema gyratum repens were non-paraneoplastic; another 29 cases were considered most likely examples of different dermatoses clinically mimicking erythema gyratum repens.¹⁷⁵¹ Accordingly, erythema gyratum repens has been reported in association with pulmonary tuberculosis,¹⁷⁵² ichthyosis,¹⁷⁵³ epidermolysis bullosa acquisita associated with ulcerative colitis,¹⁷⁵⁴ urticarial vasculitis,⁹²⁹ pegylated IFN- α for chronic hepatitis C,¹⁷⁵⁵ and in the resolving stage of pityriasis rubra pilaris.¹⁷⁵⁶ Erythema gyratum repens has followed treatment of pityriasis rubra pilaris with oral acitretin¹⁷⁵⁷ and methotrexate.¹⁷⁵⁸ It also occurs in otherwise healthy individuals.^{1759,1760}

It has been suggested that lymphokines produced by the tumor, such as epidermal growth factor, may play a role in the pathogenesis.¹⁷⁴⁹

Histopathology¹⁶⁹⁸

The findings in erythema gyratum repens are often described as ‘non-specific’. There is usually mild spongiosis with focal parakeratosis and

mild to moderate acanthosis. A sparse to moderately heavy lymphohistiocytic infiltrate is present around vessels of the superficial plexus, often associated with mild edema of the papillary dermis. Sometimes the infiltrate includes variable numbers of eosinophils. Its extension to involve the deep vascular plexus has also been reported.¹⁷⁰³ Unusual accumulations of Langerhans cells were present in the upper epidermis in one case.¹⁷⁶¹

Direct immunofluorescence often reveals the presence of granular deposits of IgG and/or C3 along the basement membrane zone, usually in a less regular pattern than occurs in bullous pemphigoid.¹⁷⁶² The deposits are beneath the lamina densa.¹⁷⁴⁹

Differential diagnosis

Basically, a diagnosis of erythema gyratum repens depends on the clinical presentation, which as mentioned is usually quite striking. However, the microscopic findings can be supportive of the diagnosis. The combination of focal parakeratosis, spongiosis, and a superficial perivascular lymphocytic and macrophagic infiltrate can also be seen in the superficial variant of erythema annulare centrifugum. Also, note that in some case reports, erythema gyratum repens has begun as a more localized annular erythema with clinical features that resemble erythema annulare centrifugum. In addition, there are reported examples of erythema annulare centrifugum that clinically mimic erythema gyratum repens.¹⁷⁶³ Histopathologic evaluation can be important in excluding other annular erythemas that might clinically mimic erythema gyratum repens, such as dermatophyte infection (organisms should be detectable in the stratum corneum with PAS or silver methenamine stains) or subacute cutaneous LE (interface rather than spongiotic dermatitis, often with dermal mucin deposition).

Erythema marginatum

Erythema marginatum is a diagnostic manifestation of rheumatic fever, seen in less than 10% of cases.¹⁷⁶⁴ It may develop at any time during the course of the disease and is more likely to occur in children than in adults. The annular eruption is macular or slightly raised, with a pink or red border and a paler center.¹⁷⁶⁵ Lesions are asymptomatic, transient, and migratory. An erythema marginatum-like eruption may precede an acute edematous episode of hereditary angioneurotic edema.¹⁷⁶⁶ Another example of erythema marginatum associated with acquired angioedema disappeared rapidly after subcutaneous administration of icatibant, a bradykinin B2 receptor antagonist.¹⁷⁶⁷

Histopathology^{1764,1765}

Erythema marginatum is included here because of its clinical appearances. The histopathological changes are not usually those of a lymphocytic vasculitis.¹⁷⁶⁸ Rather, there is a perivascular infiltrate in the upper dermis that includes many neutrophils in addition to a few lymphocytes and eosinophils. It is often said that there is no vasculitis, although mild leukocytoclasia was noted in earlier accounts of the disease.

Annular erythemas of infancy

The term ‘annular erythemas of infancy’ refers to a rare, heterogeneous group of nonpruritic, annular erythemas reported under various titles, including familial annular erythema,¹⁷⁶⁹ annular erythema of infancy,^{1770,1771} persistent annular erythema of infancy,^{1772,1773} neutrophilic figurate erythema of infancy,¹⁷⁷⁴ erythema gyratum atrophicans transiens neonatale,¹⁷⁷⁵ and infantile epidermodysplastic erythema gyratum.¹⁷⁷⁶ Clinical differences exist between all these entities. Annular erythema of infancy, the best defined of these variants, usually commences in the first weeks of life, with complete disappearance within a few months. Mild scaling and transient hyperpigmentation can follow resolution of the lesions.¹⁷⁷⁷ Several cases have been

associated with maternal lupus erythematosus.¹⁷⁷⁸ A hypersensitivity response to unrecognized antigens is suspected.¹⁷⁷⁹ Intestinal colonization with *Candida albicans* has been incriminated.¹⁷⁷³

Various treatments have been used, but there is no evidence that they have altered the course of the disease.¹⁷⁷⁷

Histopathology

Most annular erythemas of infancy show a superficial and deep lymphohistiocytic infiltrate in a perivascular distribution, as seen in the so-called 'deep gyrate erythemas'.¹⁷⁷² They differ by the presence usually of eosinophils and sometimes of neutrophils in the infiltrate. Interstitial neutrophils are numerous in the condition known as neutrophilic figurate erythema of infancy.¹⁷⁷⁴ There are also nuclear dust, perivascular lymphocytes, and a few eosinophils. Occasional interstitial eosinophils, resembling the pattern of an arthropod bite reaction, are sometimes present. Epidermal atrophy was present in one variant,¹⁷⁷⁵ whereas bowenoid features were recorded in the epidermis in another.¹⁷⁷⁶

Erythema chronicum migrans

Erythema chronicum migrans, caused by *Borrelia burgdorferi*, is discussed in detail with the spirochetal infections (see p. 680). The histopathological changes are those of a deep gyrate erythema.

PITYRIASIS LICHENOIDES

Pityriasis lichenoides is an uncommon, self-limiting dermatosis of disputed histogenesis with a spectrum of clinical changes.¹⁷⁸⁰ At one end is a relatively acute disorder with hemorrhagic papules that resolve to leave varioliform scars – pityriasis lichenoides et varioliformis acuta (PLEVA); at the other end of the spectrum is a less severe disease with small, scaly, red-brown maculopapules, known as pityriasis lichenoides chronica (PLC).^{1781,1782} The distinction between the acute and chronic forms is not always clear-cut.^{1782,1783} Pityriasis lichenoides may develop at all ages, but there is a predilection for males in the second and third decades of life. PLEVA has been reported in an infant.¹⁷⁸⁴ Lesions, which vary in number from approximately 20 to several hundred, are most common on the anterior aspect of the trunk and the flexor surfaces of the proximal parts of the extremities. In a review of 22 pediatric cases of pityriasis lichenoides, 72% were of the chronic type.¹⁷⁸⁵ In a study of 124 childhood cases reported in 2007, 37% had a chronic type, 57.3% developed PLEVA, and the remainder had overlap features of the two types.¹⁷⁸⁶ Involvement was diffuse in 74.2% of patients, peripheral in 20.2%, and central in the remainder. The median duration of the disease was 20 months (range, 3–132 months) in patients with PLC and 18 months (range, 4–108 months) with PLEVA.¹⁷⁸⁶ The disease was recurrent in 77% of patients. Another study published in 2007 compared pityriasis lichenoides in children and adults.¹⁷⁸⁷ Compared with adults, the disease in children was more likely to run an unremitting course, with greater lesional distribution, more dyspigmentation, and a poorer response to conventional therapies.¹⁷⁸⁷ No cases in these three studies or another large series¹⁷⁸⁸ progressed to lymphoma, although occasional cases of this complication have been recorded.¹⁷⁸⁹ Mycosis fungoides is the most common lymphoproliferative disorder to occur in pityriasis lichenoides; often, cases evolve through a poikilodermatous stage. A form of mycosis fungoides that clinically simulates or arises in association with pityriasis lichenoides has been reported in children. Adult cases have also been reported.^{1790,1791} Monoclonal populations of T cells can be found in both acute and chronic variants in a significant number of cases (see later),^{1792–1795} but they are much more common in PLEVA than in PLC.¹⁷⁹⁵ Magro and colleagues include pityriasis lichenoides with the T-cell dyscrasias.¹⁷⁹⁶ In another study, they found that half of all cases

of PLC showed a monoclonal and/or an oligoclonal restricted T-cell repertoire.¹⁷⁹⁷ They concluded that "the limited propensity for progression to mycosis fungoides may reflect internal countercheck mechanisms of controlling clonally-restricted CD4⁺ proliferations via CD8⁺ and CD4/CD25⁺ regulatory T cells".¹⁷⁹⁷

PLEVA

The acute form of pityriasis lichenoides (sometimes called Mucha–Habermann disease, although recently its use has been restricted to the ulceronecrotic variant – see later) is a papular eruption in which the lesions may become hemorrhagic or crusted before healing to leave a superficial varioliform scar. The lesions appear in crops that heal in several weeks; new lesions may continue to appear for many months or even years, with varying periods of remission. A severe form with ulceronecrotic lesions and constitutional symptoms has been described.^{1798–1802} Fortunately, it is quite rare, with just over 30 cases reported. Sometimes this variant is fatal.¹⁸⁰³ Transition of PLEVA to febrile ulceronecrotic Mucha–Habermann disease is associated with elevated levels of TNF- α , paving the way for the possible use of TNF- α antagonists in the treatment of this form of the disease.¹⁸⁰⁴ Clonal variants of this form of the disease have been reported.¹⁸⁰⁵ PLEVA has been reported in patients with HIV infection¹⁸⁰⁶ and has occurred in relation to infliximab therapy,¹⁸⁰⁷ subcutaneous immunoglobulin administration,¹⁸⁰⁸ and the use of hydroxymethylglutaryl-CoA reductase inhibitors.¹⁸⁰⁹ An association with the PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis) has also been reported.¹⁸¹⁰ Its association with pregnancy was possibly fortuitous.¹⁸¹¹

PLC

The chronic form is more scaly and less hemorrhagic and consists of red-brown inflammatory papules and macules with a characteristic, centrally adherent, 'mica' scale that is easily detached. An individual lesion usually regresses over a period of weeks, but as in PLEVA, there are often exacerbations and remissions that may occur over several years.¹⁷⁸⁰ Postinflammatory hypopigmentation is quite common in dark-skinned individuals.¹⁸¹² Lesions are usually found on the trunk and proximal extremities, but rare presentations have included an acral and a segmental type.^{1813–1815} It has been reported in association with multiple myeloma,¹⁸¹⁶ autoimmune hepatitis,¹⁸¹⁷ idiopathic thrombocytopenic purpura,¹⁸¹⁸ measles–mumps–rubella vaccination,¹⁸¹⁹ and herpes simplex virus type 2.¹⁸²⁰

The pathogenesis of pityriasis lichenoides is unknown: cell-mediated immune mechanisms, possibly related to viral^{1821–1823} or other infections,^{1824–1826} may be important.¹⁸²⁷ Infections have included Epstein–Barr virus (EBV),¹⁸²⁸ parvovirus B19,¹⁸²⁹ adenovirus, herpes zoster–varicella virus,¹⁸³⁰ HIV,¹⁸³¹ *Toxoplasma gondii*, *S. aureus*, and group A β -hemolytic streptococci.¹⁸¹⁸ It is usually regarded as a lymphocytic vasculitis. Its relationship to lymphomatoid papulosis is controversial. The favored view is that the two diseases are pathogenetically distinct,^{1831,1832} although both are part of the spectrum of clonal T-cell lymphoproliferative disorders.^{1792,1833} A case has been reported of type B lymphomatoid papulosis that was followed 11 years later by the development of pityriasis lichenoides.¹⁸³⁴ The close relationship between the two is further underscored by reports of PLEVA with numerous CD30⁺ cells, some of which coexpressed CD8. This finding was considered to be consistent with an inflammatory antiviral response, further suggested by the identification of parvovirus B19 in 4 of 10 cases studied.¹⁸³⁵ In addition to the infectious and lymphoproliferative theories of pathogenesis, a third etiology has been postulated, namely an immune complex-mediated vasculitis. Immune complexes have not been found by some investigators, so this is the least favored view.¹⁷⁸⁰

Pityriasis lichenoides is usually treated in the first instance with oral antibiotics and topical corticosteroids or immunomodulators, particularly methotrexate. Erythromycin¹⁷⁸⁶ and tetracyclines are the antibiotics most often used, but azithromycin was successful in one case in which these two antibiotics produced no response.¹⁸³⁶ Second-line therapy includes UVA,¹⁸³⁷ UVB,¹⁸³⁸ or photodynamic therapy.¹⁸³⁹ Oral cyclosporine, methotrexate, and methylprednisolone semipulse therapy may be used for the ulceronecrotic form.^{1840,1841}

Histopathology^{1831,1842}

Pityriasis lichenoides is essentially a lymphocytic vasculitis in which the associated inflammatory cell infiltrate shows exocytosis into the epidermis with obscuring of the dermoepidermal interface.¹⁸⁴³ There is variable death of epidermal keratinocytes that may involve scattered single cells or sheets of cells, resulting in confluent necrosis of the epidermis.¹⁸⁴⁴ Some of the keratinocytes undergo apoptosis. The inflammatory infiltrate and the degree of epidermal changes are more prominent in PLEVA than in pityriasis lichenoides chronica. Cases anywhere along this spectrum can occur. In summary, both are lichenoid (interface) dermatitides with lymphocytic vasculitis (lichenoid lymphocytic vasculitis).

In PLEVA, there is a sharply delimited, sparse to moderately dense inflammatory cell infiltrate involving the superficial vascular plexus. Sometimes this extends in a wedge-shaped pattern to also involve the lower dermis. The infiltrate is composed of lymphocytes and some macrophages; in florid cases, there may be some perivascular neutrophils as well and even a leukocytoclastic vasculitis.¹⁸⁰⁰ A few atypical lymphoid cells may be found in a small number of cases. There is endothelial swelling involving small vessels and extravasation of red blood cells. Only occasionally do the vessels show 'fibrinoid necrosis'. The papillary dermis is variably edematous.

Lymphocytes and some erythrocytes extend into the epidermis (Fig. 8.30). This is associated with some basal vacuolar change and spongiosis.¹⁸⁴² Degenerate keratinocytes are not restricted to the basal layer, and they are often more prominent in the upper layers of the epidermis. In advanced lesions, there is often extensive epidermal necrosis. Overlying parakeratosis is quite common, and there may be some neutrophils forming a parakeratotic crust. Dermoscopy of PLEVA shows a central whitish patch or crust and a surrounding ring of vascular structures that are dilated and convoluted, some in a glomerular or linear arrangement, and with nonblanchable reddish globules.¹⁸⁴⁵

In PLC, the infiltrate is less dense and more superficial than in PLEVA, and the epidermal changes are much less pronounced.^{1846,1847} There is a relatively sparse perivascular infiltrate with only subtle, if any, features of a lymphocytic vasculitis. A few extravasated erythrocytes may be present. There are small areas of basal vacuolar change associated with minimal exocytosis of lymphocytes and occasional degenerate keratinocytes.

The epidermis shows variable acanthosis and is sometimes vaguely psoriasiform. Pallor of the upper epidermis may be noted, with overlying parakeratosis. Late lesions may show mild fibrosis of the papillary dermis and the presence of some melanophages – changes that are also found in late lesions of PLEVA.

Immunofluorescence reveals the presence of immunoreactants, particularly IgM and C3, along the basement membrane zone and in vessels of the papillary dermis in a small number of cases.¹⁸⁴⁸ Immunoperoxidase studies have shown that the lymphocytes in the dermal infiltrate are T cells, particularly of the cytotoxic/suppressor (CD8) type in PLEVA, although CD4⁺ cells appear to predominate in the chronic form.¹⁷⁹² Another study found a predominance of CD8⁺ cells in both forms of the disease.¹⁸²⁹ Approximately 5% of the perivascular cells are Langerhans or indeterminate cells.¹⁸²⁷ CD1a⁺ cells are also increased in the epidermis. Cases with CD30⁺ cells have been reported.^{1849–1851} The epidermis in the lesions is HLA-DR positive.¹⁸⁴⁷

Figure 8.30 (A) Pityriasis lichenoides. (B) In this acute variant, there is a lichenoid reaction pattern with 'interface obscuring'. (C) Another case with parakeratosis overlying the interface changes. (H&E)

Differential diagnosis

When all the classic findings of PLEVA are present, they are sufficiently characteristic to enable a microscopic diagnosis, even when there is minimal clinical information. The changes can sometimes closely mimic erythema multiforme, in which case the exclusion of the latter diagnosis can be quite difficult without clinical information. Helpful findings favoring PLEVA include significant exocytosis and sometimes deep, wedge-shaped as well as superficial perivascular dermal infiltrates with lymphocytic vasculitis. There can be some microscopic as well as clinical resemblance to lymphomatoid papulosis; in fact, some early authors initially described the latter as pityriasis lichenoides with atypia. Generally, the degree of cytologic atypia among lymphoid cells in lesions of lymphomatoid papulosis is quite striking – more severe and extensive than would be expected in PLEVA. However, there may be a problematic degree of atypia in the severe ulceronecrotic variant of pityriasis lichenoides, and, as noted, positive T-cell receptor gene rearrangements are sometimes found in PLEVA. This could potentially create diagnostic issues but, as noted previously, also suggests that these conditions may fall within different points of a spectrum of T-cell lymphoid dyscrasias. The problem in pityriasis lichenoides chronica is often that the changes are quite mild, and thus a wide array of dermatoses – including forms of spongiotic dermatitis, drug reactions, or digitate dermatosis – are often part of the differential diagnosis. In these circumstances, it is helpful to search for the more diagnostic findings of PLEVA in such lesions (e.g., subtle lymphocytic vasculitis, occasional apoptotic keratinocytes, and erythrocytes within the epidermis); they are often present, but to a lesser degree.

PIGMENTED PURPURIC DERMATOSES

The pigmented purpuric dermatoses (PPDs) are a group of chronic skin disorders with overlapping clinical and histopathological features.^{1852–1855} The lesions are purpuric, with variable pigmentation resulting from the deposition of hemosiderin, which is, in turn, a consequence of the extravasation of red blood cells from capillaries in the papillary dermis. There is a predilection for the lower extremities of young adults, but cases have also been reported in children.¹⁸⁵⁶ Six clinical variants have been recognized. Some cases defy classification into one of these groups, such as the unilateral linear cases first reported some years ago^{1857,1858} and cases with a zosteriform or segmental distribution.^{1859,1860} A transitory and a granulomatous variant have also been described, making 12 distinct types if the eczematid and itching variants (discussed later) are regarded as distinct entities.¹⁸⁶¹

Progressive pigmentary dermatosis (Schamberg's disease)

Progressive pigmentary dermatosis is the most common type.¹⁸⁵⁴ There are numerous punctate purpuric macules forming confluent patches. These are usually symmetrically distributed in the pretibial region. Familial cases^{1862,1863} and a unilateral distribution have been described.^{1864,1865} An association with morphea has been reported.¹⁸⁶⁶ Persistence of lesions for up to 7 years or more may occur.¹⁸⁶⁷ The eczematid-like purpura of Doucas and Kapetanakis,^{1868,1869} the itching purpura of Loewenthal,¹⁸⁷⁰ and disseminated pruriginous angiodermatitis¹⁸⁷¹ are now regarded as variants of Schamberg's disease. These pruritic forms usually have an acute onset and a self-limited course.

Purpura annularis telangiectodes of Majocchi

There are annular patches with perifollicular, red punctate lesions, and telangiectasias.¹⁸⁵³ A familial case has been reported.^{1872,1873}

Pigmented purpuric lichenoid dermatosis of Gougerot and Blum

Pigmented purpuric lichenoid dermatosis of Gougerot and Blum consists of lichenoid papules that may coalesce to give plaque-like lesions. They are often symmetrically distributed on the lower legs.¹⁸⁵³ If uni-

lateral, the plaque may mimic Kaposi's sarcoma.¹⁸⁷⁴ Hepatitis C infection is a rare association.¹⁸⁷⁵

Lichen aureus

Lichen aureus is closely related to the Gougerot and Blum variant (discussed above). There are grouped macules or lichenoid papules having a rusty, golden, or even purplish color.^{1876,1877} Lesions may occur on the trunk or upper extremity, although the lower parts of the legs are the site of predilection.^{1878,1879} Involvement of the glans penis has been reported.¹⁸⁸⁰ Agminated¹⁸⁸¹ and segmental¹⁸⁸² lesions have also been described. Lichen aureus is usually unilateral.^{1877,1883} Diagnosis can be made on dermoscopy.¹⁸⁸⁴ Slow, spontaneous resolution occurs over a period ranging from 1 to 12 years.¹⁸⁵⁶ The coexistence of lichen aureus and familial Mediterranean fever has been reported.¹⁸⁸⁵ A multifocal case has followed the almost daily consumption of an energy drink containing caffeine, taurine, glucuronolactone, and B-complex vitamins.¹⁸⁸⁶

Purpuric contact dermatitis

Purpuric contact dermatitis is not well-known. It is a form of allergic contact dermatitis to textile dyes and resins in personal clothing.¹⁸⁸⁷ Sometimes an impressive pattern of purpura and hemosiderotic pigmentation is distributed in clothed areas. The dyes Disperse Blue and Disperse Red have been incriminated on many occasions.^{1887,1888} Similar lesions have been reported with exposure to the American aloe or century plant (*Agave americana*).¹⁸⁸⁹

PPD/mycosis fungoides overlap

There appears to be a relationship between some cases of persistent PPD and mycosis fungoides.¹⁸⁹⁰ LeBoit¹⁸⁹¹ summarized the dilemma in the title of a paper in 1997 – “Simulant, precursor, or both?” His group reported patients with a PPD that presented clinically as mycosis fungoides as well as patients who had features of both conditions.¹⁸⁹¹ Clonal populations of lymphocytes were present in 8 of 12 specimens that were typical of the lichenoid patterns of PPD.¹⁸⁹¹ Others have reported cases of mycosis fungoides that presented clinically as PPD.^{1892–1894} In one case, a patient with mycosis fungoides developed both hypopigmented and pigmented purpura-like lesions.¹⁸⁹⁵ Crowson and colleagues found that several classes of drugs, including calcium channel blockers, ACE inhibitors, lipid-lowering agents, β -blockers, antihistamines, antidepressants, and analgesics, could produce a histologically atypical pigmentary purpura (including clonality in two cases) that resolved on cessation of the drug.¹⁸⁹³ Magro and colleagues studied 43 cases of PPD in 2007.¹⁴⁸² Of these cases, 22 were polyclonal. In this group, disease outside the lower extremities was uncommon, and there were no patients with mycosis fungoides. The remaining 21 cases were monoclonal variants. Monoclonal cases had extensive skin lesions. Approximately 40% of the monoclonal cases had clinical and pathological features of mycosis fungoides.¹⁴⁸² On the basis of these cases and the frequency of monoclonality, the authors concluded that this disease is a form of “T-cell lymphoid dyscrasia”.^{1482,1896} In contrast, a study from Graz, Austria, of 23 patients with lichen aureus found a monoclonal T-cell population in half of the patients tested, but there was no progression to mycosis fungoides.¹⁸⁹⁷

Three different pathogenetic mechanisms have been proposed for the PPDs:¹⁸⁹⁸ (1) disturbed humoral immunity; (2) cellular immune reactions (delayed hypersensitivity) related to the dermal infiltrate of lymphocytes, macrophages, and Langerhans cells;^{1898,1899} and (3) weakness of blood vessels with increased capillary fragility.¹⁹⁰⁰ Perforator vein incompetence was present in one series of cases of lichen aureus.¹⁹⁰¹ There is increased expression of cellular adhesion molecules in lesional skin; a similar pattern can be seen in delayed hypersensitivity reactions.^{1902,1903} There are isolated reports implicating sensitivity to oils used in wool processing; exposure to dyes (discussed previously);¹⁹⁰⁴ and treatment with thiamine,¹⁹⁰⁴ carbromal, meprobamate,

benzafibrate,¹⁹⁰⁵ diuretics, ampicillin, nonsteroidal anti-inflammatory drugs,¹⁸⁵⁴ amantadine, acetaminophen (paracetamol),¹⁹⁰⁶ infliximab,¹⁸⁵⁹ herbal remedies, creatine supplementation,¹⁹⁰⁷ glipizide,¹⁹⁰⁸ and medroxyprogesterone acetate.^{1909,1910} Other drug classes have been incriminated in producing so-called 'atypical pigmentary purpura' (discussed previously). Chronic odontogenic infection has also been incriminated.¹⁹¹¹ Antibodies to the hepatitis B and the hepatitis C virus have been present in a few cases,¹⁹¹² but a recent case-control study indicates that direct involvement of these viruses in the pathogenesis of pigmented purpuric dermatosis is unlikely.¹⁹¹³

Bioflavonoids and ascorbic acid, both of which increase capillary resistance, have been shown to have a beneficial effect in some cases.¹⁹¹⁴ Topical corticosteroids are ineffective. One case showed a response to topical tacrolimus.¹⁹¹⁵ Narrowband UVB has been used alone and as an adjuvant while patients are being weaned off systemic corticosteroids.^{1916–1918} Pulsed light therapy,¹⁹¹⁹ colchicine,¹⁸⁷³ oral cyclosporine, and griseofulvin have been effective in some cases. Segmental lichen aureus has been treated with pentoxifylline and prostacyclin.¹⁹²⁰

Histopathology

There is a variable infiltrate of lymphocytes and macrophages in the upper dermis. This is band-like and heavy in lichen aureus, and it is less dense and with perivascular accentuation in the other variants (Figs. 8.31 and 8.32). In one case of lichen aureus, there were also perineural and periappendageal lymphocytic infiltrates.¹⁹²¹ A lymphocytic vasculitis involving vessels in the papillary dermis is often present in active cases (Fig. 8.33). Some authors do not accept this condition as a lymphocytic vasculitis because of the absence of fibrin.¹⁸⁵⁴ However, fibrin is not a prerequisite for the diagnosis of chronic inflammation in any other organ system. Carlson groups it as a "pseudovasculitis".¹⁹²² The infiltrate is composed predominantly of T lymphocytes, a majority of which are CD4⁺, admixed with some reactive CD1a⁺ dendritic cells.^{1898,1903,1923} Plasma cells are sometimes present in lichen aureus, whereas a few neutrophils are usually seen in the infiltrate in the lesions of itching purpura (Fig. 8.34). In the rare granulomatous variant, the noncaseating granulomas of tuberculoid type are present in the papillary dermis.¹⁹²⁴ This variant has most often been reported in Asians, most of whom had hyperlipidemia,¹⁹²⁵ but several examples have now been described in non-Asian patients.¹⁹²⁶ There is

Figure 8.32 Pigmented purpuric dermatosis. (A) The infiltrate is less heavy in this case. Hemosiderin pigment can just be discerned. (B) There is red cell extravasation and very focal, mild interface change. (H&E)

Figure 8.31 Pigmented purpuric dermatosis. This condition is characterized by an infiltrate that fills the papillary dermis. Tight lymphocytic cuffing of vessels in the papillary dermis is often present. (H&E)

Figure 8.33 Pigmented purpuric dermatosis. A lymphocytic vasculitis is present. It is not always as obvious as in this case. (H&E)

Figure 8.34 Itching purpura. There is extravasation of erythrocytes and mild cuffing of small vessels in the papillary dermis by lymphocytes. (H&E)

often exocytosis of lymphocytes and associated spongiosis of the epidermis in all variants except lichen aureus; in the latter, a thin layer of uninvolved collagen separates the undersurface of the epidermis from the inflammatory infiltrate below.¹⁹²⁷ When spongiosis is present, there is often focal parakeratosis as well.

There is variable extravasation of red blood cells into the papillary dermis. Hemosiderin is present, predominantly in macrophages, although small amounts are sometimes found lying free in the papillary dermis and even in the epidermis. Sometimes the macrophages containing the hemosiderin are at or below the lower margin of the inflammatory infiltrate, but the hemosiderin is never as deep in the dermis as in stasis dermatitis except in the form with deep plexus involvement, which is an uncommon variant. In this type, the hemosiderin shows perivascular accentuation, which distinguishes it from the more diffuse deposits seen in venous stasis.¹⁸⁵² In long-standing (chronic) cases of PPD, deep extension of the pigment will occur, but the deposition is still 'top heavy'. Hemosiderin is usually absent in early lesions of itching purpura. Blood vessels in the papillary dermis may be dilated, but more often there is endothelial swelling causing luminal narrowing. Occasionally, there is hyaline thickening of blood vessel walls or pericapillary fibrosis. Hemosiderin takes at least 10 days to accumulate in sufficient amounts to be seen, after the onset of red cell extravasation; it may not be present in early lesions.

With dermoscopy, lesions of lichen aureus show a coppery-red diffuse background coloration, round to oval red dots, globules and patches, gray dots, and a network of brown to gray interconnected lines.¹⁸⁸⁴ All of these features are not necessarily seen in every case.¹⁹²⁸ Immunofluorescence studies have usually been negative, except for the presence of perivascular fibrin. In one study, C3 and, sometimes, immunoglobulins were present in vessel walls.¹⁹²⁹ Cases associated with an IgA-associated lymphocytic vasculopathy have been reported.¹⁶³⁵

Electron microscopy

Ultrastructural studies have not contributed in any way to our understanding of these dermatoses.¹⁹³⁰ Langerhans cells have been identified in the inflammatory infiltrate.

Differential diagnosis

Diagnosis of PPDs is generally not difficult, although in early lesions the microscopic changes can be disproportionately subtle when compared to fairly obvious clinical disease. Some degree of small vessel proliferation in the superficial dermis is often encountered in biopsies

of the lower extremities of adults; this often represents merely background change and is frequently a clue to that particular anatomic location. Patients with chronic venous stasis or stasis dermatitis often show superficial dermal changes of pigmented purpura. In addition, they often have significant epidermal (acanthosis and ulceration) or dermal (sclerosis and aggregations of thick-walled vessels in the mid to deep dermis) changes. The uncommon granulomatous variant of pigmented purpuric dermatosis can be confused with other granulomatous disorders or forms of lichenoid and granulomatous dermatitis. A case of purpuric papulonodular sarcoidosis mimicking pigmented purpura has been reported.¹⁹³¹ The diagnosis of sarcoidosis was supported by the finding of multiple small pulmonary nodules on CT scan, and skin biopsy specimens showed sarcoid granulomas in the superficial dermis with erythrocyte extravasation but only a sparse rim of lymphocytes around the granulomas and no vasculitic changes. This is in contrast to the usual lymphocytic infiltrates and vessel changes in PPDs, including the granulomatous variant.¹⁹³¹ The histological overlap between mycosis fungoides and PPDs, particularly those with lichenoid features, is well-known. Both are part of the LUMP mnemonic that lists diseases with infiltrates filling the papillary dermis – lichenoid disease, urticaria pigmentosa, mycosis fungoides and precursors, and the pigmented purpuric dermatoses. Features favoring PPDs in these overlap cases and simulants include lack of atypia and papillary dermal fibrosis and the presence of mild edema in the papillary dermis. Both can show epidermotropism, but in mycosis fungoides this usually extends higher than the basal layer of cells.¹⁸⁹¹ Furthermore, in mycosis fungoides the intraepidermal lymphocytes appear more atypical than the dermally based ones.¹⁸⁹³ In some cases, a diagnosis of mycosis fungoides/PPD overlap is the best that can be given in our current state of knowledge (Fig. 8.35). Clonality is not always a predictor of outcome, at least in the relative short term.¹⁹³²

MALIGNANT ATROPHIC PAPULOSIS

Malignant atrophic papulosis (Degos disease) is a rare, often fatal, multisystem vaso-occlusive disorder in which pathognomonic skin lesions are frequently associated with infarctive lesions of other viscera, particularly the gastrointestinal tract.^{1933,1934} Fewer than 200 cases have been reported.^{1935,1936} Patients develop crops of papules, approximately 0.5–1 cm in diameter, which evolve slowly to become umbilicated with a porcelain white center and a telangiectatic rim and finally leave an atrophic scar.¹⁹³⁷ There are approximately 10–40 lesions at any time, in different stages of evolution. More than 600 papules may be present.¹⁹³⁸ Penile ulceration was the mode of presentation in one case.¹⁹³⁹ It may also be a component of more widespread cutaneous disease.¹⁹⁴⁰ In 60% or more of cases, gastrointestinal involvement supervenes, usually within 1 year but sometimes after a long interval.^{1934,1941,1942} Approximately 15% of patients have only cutaneous lesions and a relatively benign course.^{1943–1950} Involvement of the central nervous system may also occur;^{1935,1951} less commonly, other viscera also develop infarcts.¹⁹⁵² There are several reports of familial involvement,^{1953–1955} including one in which the mother and five children were affected.¹⁹⁵⁶ It has also been reported in an infant.¹⁹⁵⁷ It has developed in a patient with AIDS.¹⁹⁵⁸ In another patient, onset occurred in pregnancy,¹⁹⁴⁸ and in still another the disorder followed an upper respiratory streptococcal infection.¹⁹⁵⁹

Malignant atrophic papulosis has been regarded as an 'endovasculitis' or primary endothelial defect,¹⁹⁶⁰ with secondary thrombosis leading to infarctive lesions.¹⁹⁶¹ Impaired fibrinolytic activity and alterations in platelet function have been detected,^{1962,1963} but there are no circulating immune complexes¹⁹⁶⁰ or antiendothelial cell antibodies. Anticardiolipin antibodies are sometimes present.^{1964–1966} Most authors agree that the condition is not a vasculitis in the sense that allergic vasculitis and polyarteritis nodosa are;¹⁹⁶⁰ however, a study of ultrathin sections led

Figure 8.35 (A) Mycosis fungoides/pigmented purpuric dermatosis overlap. (B) Epidermotropism is quite marked. (H&E) (C) The same case showing abundant hemosiderin pigment. (Perls stain)

to the conclusion that it is a lymphocyte-mediated necrotizing vasculitis.¹⁹⁶⁷ Malignant atrophic papulosis has also been regarded as a mucinosis,¹⁹³³ but the deposition of mucin is only a secondary phenomenon. Ackerman believes that it is mostly an expression of lupus erythematosus, but uncommonly it may be a manifestation of other diseases,

Figure 8.36 Malignant atrophic papulosis. There is a wedge-shaped area of altered epidermis and dermis with a lymphocytic vasculitis at the apex near the dermal-subcutaneous junction. (H&E)

such as rheumatoid arthritis or dermatomyositis. He believes that it is not a disease sui generis.¹⁹⁶⁵ Others have since confirmed this viewpoint.^{1968,1969}

Many cases have responded to aspirin and dipyridamole.¹⁹⁶⁹ Heparin has been used for the acutely ill. Other therapies, such as plasma exchange, intravenous immunoglobulin,¹⁹⁷⁰ corticosteroids, and other systemic immunosuppressants, have been largely, but not always,¹⁹⁷⁰ unsuccessful.^{1942,1969} Initially promising results have been obtained with eculizumab and treprostinil.¹⁹⁷¹

Histopathology^{1934,1967}

A well-developed lesion shows epidermal atrophy with overlying hyperkeratosis and an underlying wedge-shaped area of cutaneous ischemia, the apex of which extends into the deep dermis (Fig. 8.36). This dermal area is uniformly hypereosinophilic and relatively acellular. A mild to moderately dense lymphocytic infiltrate is present at the edge of the ischemic wedge, particularly in the mid and lower dermis.^{1943,1967} The infiltrate has a perivenular and intervenular distribution. There is marked endothelial swelling of venules and, to a lesser extent, arterioles, sometimes with obliteration of the lumen. There are fibrin-platelet thrombi in some small vessels, and there is some perivenular distribution of fibrin in the dermis.^{1967,1972} A study using thin sections has also shown ghost-like infarcted small vessels and demyelination of cutaneous nerves.¹⁹⁶⁷ Red cells fill the lumen of some small vessels. A panniculitis mimicking lupus profundus has been reported in one patient (see p. 542).

Sometimes the epidermis shows focal infarction or scattered necrotic keratinocytes in addition to the atrophy. There may also be some basal vacuolar change (Fig. 8.37). The late-stage changes closely resemble a miniaturized version of lichen sclerosus et atrophicus.¹⁹⁴⁶

A prominent feature is the presence of abundant acid mucopolysaccharides in the dermis.¹⁹³³ Initially, these are localized to the ischemic zone, but in older lesions the material is confined to the margins of this zone. They stain with the colloidal iron or Alcian blue methods.

Immunofluorescence studies have given conflicting results. Fibrin is always demonstrated, and sometimes immunoglobulins and complement may be found around small dermal vessels or near the basement membrane.¹⁹⁶⁷

Electron microscopy

There is swelling of endothelial cells with various degenerative changes¹⁹⁶⁷ and sometimes luminal occlusion by endothelial cells and

Figure 8.37 Malignant atrophic papulosis. The epidermis overlying the wedge-shaped area of ischemia is markedly thinned, and in this case shows occasional necrotic keratinocytes and vacuolar alteration of the basilar layer with focal subepidermal separation. (H&E)

cell fragments. Tubular aggregates are often seen in the endothelial cells.¹⁹⁷³

PERNIOSIS

Perniosis is a localized inflammatory lesion that develops in certain individuals exposed to cold temperatures.^{1974–1977} Classic perniosis (chilblains) occurs on the fingers and toes, and sometimes the ears, but plaques have also been described on the thighs.¹⁹⁷⁵ Lupus erythematosus is uncommonly complicated by lesions mimicking perniosis (chilblain lupus).¹⁹⁷⁸ A congenital form of chilblain lupus also occurs (see p. 68). An association with chronic myelomonocytic leukemia, viral hepatitis, celiac disease, HIV infection, and rheumatoid arthritis has been reported.^{1979–1981} Perniosis can be clinically mimicked by leukemia cutis, but leukemic cells can be readily identified in the dermis in these cases.¹⁹⁸²

Equestrian perniosis is the term used for a particular form of perniosis that occurs on the buttocks and lateral thighs of female horse riders in the winter.¹⁹⁸³ Cryoproteins may be present in these horse riders and in children with perniosis.^{1983,1984}

A perniotic-like reaction has been reported following the use of the amphetamine analogues fenfluramine and phentermine for weight reduction.¹⁹⁸⁵

Histopathology¹⁹⁷⁵

Perniosis is a lymphocytic vasculitis in which there is edema and thickening of vessel walls associated with a mural and perivascular infiltrate of lymphocytes (Fig. 8.38). Fibrin is not always present, but as stated previously, it is not a prerequisite for the diagnosis of a lymphocytic vasculitis. A few neutrophils and eosinophils may be present in early lesions; the presence of a leukocytoclastic vasculitis is rare.¹⁹⁸⁶ The term ‘fluffy edema’ has been used to describe the vessel wall changes.¹⁹⁷⁵ Usually, vessels at all levels of the dermis are involved, whereas at other times the process is confined to the more superficial vessels. Vascular ectasia may be present. There is variable edema of the papillary dermis, which is sometimes quite intense.¹⁹⁷⁵ Basal vacuolar change and interface dermatitis are present in lupus-related perniosis,¹⁹⁷⁸ but it is usually more widespread than the focal interface change that can be seen in idiopathic perniosis.

In summary, perniosis usually presents with a superficial and deep lymphocytic vasculitis, subepidermal edema, and perieccrine lymphocytic infiltrates, with or without interface change.⁹⁰⁵ These changes are not seen in lupus erythematosus.¹⁹⁸⁷

Differential diagnosis

Fully developed changes are rather characteristic of perniosis, but lesser degrees of perivascular inflammation could be confused with a variety of dermatoses that show perivascular infiltrates. In contrast to idiopathic perniosis, those cases associated with an autoimmune disease consistently lack perieccrine lymphocytic infiltrates; thus, this can be a useful differentiating feature.¹⁹⁸⁸ Some focal vacuolar alteration of the basilar layer overlying the dermal changes can be seen in ordinary perniosis and does not necessarily indicate a diagnosis of LE. However, extensive interface changes should raise the possibility of the latter disorder, and correlation with other clinical and laboratory findings may then be necessary. Equestrian panniculitis differs from other types in that the perivascular lymphocytic infiltrates are prominent within the subcutaneous fat.¹⁹⁸⁹

RICKETTSIAL AND VIRAL INFECTIONS

A lymphocytic vasculitis, often associated with fibrin extravasation, is characteristic of the maculopapular rash of the various rickettsial infections. If an eschar is present, necrosis of the epidermis and upper dermis will be found, with a vasculitis at the periphery of the lesion. Fibrin thrombi are often present in these vessels.

Herpesvirus and other viral infections may be associated with a lymphocytic vasculitis.¹⁹⁹⁰ A lichenoid lymphocytic vasculitis can be seen in some recurrent and persistent herpesvirus infections and in persistent reactions to certain viruses (see p. 255).

PYODERMA GANGRENOSUM

Pyoderma gangrenosum is a clinically distinctive disorder characterized by the development of an erythematous pustule or nodule that rapidly progresses to become a necrotic ulcer with a ragged, undermined, violaceous edge.^{1991–1994} Lesions may be single or multiple.¹⁹⁹⁵ Although most ulcers are less than 3 cm in diameter, large lesions up to 20 cm or more in diameter may result from coalescence of smaller ulcers.¹⁹⁹⁵ Not infrequently, minor trauma may initiate the onset of a lesion – a process known as pathergy.^{1996,1997} In addition to the ulcerative variant that comprises approximately 85% of all cases, other clinicopathological variants include pustular,¹⁹⁹⁸ bullous, vegetative,^{1999,2000} and superficial granulomatous types.²⁰⁰¹ The transition of one type into another supports the notion that these clinical forms are part of a single clinical spectrum.²⁰⁰²

Pyoderma gangrenosum has a predilection for the lower extremities,¹⁹⁹² although sometimes the trunk, and rarely the head and neck,^{2000,2003,2004} may also be involved. The retrosternal region,²⁰⁰⁵ the penis, and the eyelid are rare sites of involvement.^{2006–2009} Extracutaneous manifestations include sterile pyoarthrosis,²⁰¹⁰ oropharyngeal involvement,²⁰¹¹ splenic abscesses,²⁰¹² neutrophilic myositis,²⁰¹³ and pulmonary inflammatory infiltrates.^{2014,2015} Onset is usually in mid-adult life, but childhood onset has been recorded.^{2004,2016–2023} Onset in pregnancy may be fortuitous.²⁰²⁴ Infantile disease is exceedingly rare,^{2025–2027} as is familial occurrence.²⁰²⁸

In cases associated with hematological malignancies, the lesions may develop bullae at the advancing edge – *bullous pyoderma gangrenosum*.^{2029–2035} This clinical variant is histogenetically similar to Sweet’s syndrome, and cases with overlap features have been recorded. Patients with pyoderma gangrenosum associated with myelodysplastic syndrome and those with acute myelogenous leukemia may show the

Figure 8.38 (A) Perniosis. (B) There is subepidermal edema. **(C)** There is a lymphocytic vasculitis. Fibrin was present in a larger vessel in the upper subcutis. (H&E)

abnormality in the nuclei of their neutrophils known as the pseudo-Pelger–Huët anomaly.²⁰³⁶ A case of bullous pyoderma gangrenosum has been recorded after G-CSF treatment.²⁰³⁷ This group of patients with bullous lesions usually has a poor prognosis,²⁰³¹ but some respond to oral corticosteroids.²⁰³⁸

Another clinical variant is *malignant pyoderma*, which is a rare, ulcerating, destructive condition of the skin of the head, neck, and upper part of the trunk but which has a predilection for the preauricular region.^{1996,2039–2041} Individual lesions lack the undermined, violaceous border of pyoderma gangrenosum, and there is usually no associated systemic disease.^{2039,2042} It has been suggested that malignant pyoderma is a variant of Wegener's granulomatosis rather than pyoderma gangrenosum.²⁰⁴³ The c-ANCA has been positive in several cases.²⁰⁴¹ It has also been positive in the more usual form of pyoderma gangrenosum.²⁰⁴⁴ Particularly necrotizing lesions can be confused with necrotizing fasciitis.²⁰⁴⁵

Another clinicopathological variant has been reported as *superficial granulomatous pyoderma* (vegetative pyoderma gangrenosum).^{2046–2053} It is characterized by a superficial ulcer, usually solitary and on the trunk. It may arise at sites of surgical incision or other pathergic stimuli. Draining sinuses may be present.²⁰⁴⁶ It has been reported in a patient with chronic renal failure.²⁰⁵⁴ It runs a chronic course, although it usually responds to topical therapy.²⁰⁴⁷

Pyoderma gangrenosum can occur in an autosomal dominant condition known as the **PAPA syndrome** – pyogenic sterile arthritis, pyoderma gangrenosum, and acne (OMIM 604416).²⁰⁵⁵ It can also occur in association with chronic multifocal osteomyelitis.²⁰⁵⁶ PAPA is due to a mutation in the *CD2BP1* (*PSTPIP1*) gene on chromosome 15q24–q25.1. It is one of the autoinflammatory syndromes. The gene encodes CD2-binding protein 1 (CD2BP1), which binds pyrin.⁹⁷¹

In more than half of the cases of pyoderma gangrenosum, there is an associated systemic illness such as ulcerative colitis,^{2057,2058} Crohn's disease,^{267,2057,2059,2060} collagenous colitis,^{2061–2063} rheumatoid arthritis,¹⁹⁹² seronegative polyarthritis, or a monoclonal gammopathy, particularly of IgA type.^{150,2064} In one patient with seronegative rheumatoid arthritis, pyoderma gangrenosum developed while the patient was receiving treatment with adalimumab.²⁰⁶⁵ It has also followed the use of the tyrosine kinase inhibitor sunitinib.²⁰⁶⁶ Parastomal lesions are an important complication of inflammatory bowel disease.^{2067,2068} Rare clinical associations²⁰⁶⁹ have included chronic active hepatitis,²⁰⁷⁰ chronic persistent hepatitis,²⁰⁷¹ hepatitis C infection,^{1992,2073} sarcoidosis,²⁰⁷⁴ SLE,²⁰⁷⁵ systemic sclerosis,²⁰⁷⁶ anticardiolipin antibodies,²⁰⁷⁷ hidradenitis suppurativa (acne inversa),^{1992,2078–2080} Behçet's disease,^{2081,2082} Cogan's syndrome,²⁰⁸³ Cushing's disease,²⁰⁸⁴ a venous leg ulcer,²⁰⁸⁵ seat belt trauma,²⁰⁸⁶ Takayasu's arteritis,^{2087,2088} *Chlamydia pneumoniae* infection,²⁰⁸⁹ subcorneal pustular dermatosis,^{2090,2091} isotretinoin therapy

for acne,²⁰⁹²⁻²⁰⁹⁴ internal cancer,²⁰⁹⁵⁻²⁰⁹⁷ diabetes mellitus,²⁰⁹⁸ polycythemia rubra vera,²⁰⁹⁹ pure red cell aplasia,²¹⁰⁰ myelofibrosis,²¹⁰¹ childhood acute lymphoblastic leukemia,²¹⁰² autoimmune hemolytic anemia,²¹⁰³ IgA paraproteinemia,^{2011,2012,2104,2105} paroxysmal nocturnal hemoglobinuria,²¹⁰⁶ and postoperative²¹⁰⁷⁻²¹¹⁰ and immunosuppressed states,^{2111,2112} including HIV infection.^{2113,2114} Secondary infection with herpes simplex has occurred.²¹¹⁵ Pyoderma gangrenosum-like lesions may be a presenting sign of cutaneous T-cell lymphoma²¹¹⁶ and of Wegener's granulomatosis.²¹¹⁷ Pyoderma gangrenosum may mimic cutaneous tuberculosis.²¹¹⁸ It has followed facial plastic surgery that was combined with a silicone prosthesis implant in the breast.²¹¹⁹ It has also developed in a cholecystectomy wound,²¹²⁰ near an arteriovenous dialysis shunt,²¹²¹ and in a breast surgery wound.^{2122,2123} It may masquerade as dermatitis artefacta.²¹²⁴

Pyoderma gangrenosum may run an acute progressive course with rapidly expanding lesions that require systemic treatment to arrest their growth.^{2125,2126} Ecthyma gangrenosum and varicella have complicated pyoderma gangrenosum.^{2127,2128} Other cases pursue a more chronic course with slow extension and sometimes spontaneous regression after weeks or months.²¹²⁵ The recurrence rate in one series was 46% regardless of the treatment used.²¹²⁹ Lesions eventually heal, leaving a parchment or cribriform scar. Ulcers due to other causes may sometimes mimic pyoderma gangrenosum.^{2130,2131} Large ulcers occurring on the scrotum in children and adolescents and called **juvenile gangrenous vasculitis of the scrotum** are probably a manifestation of pyoderma gangrenosum.²¹³²

Multiple abnormalities of humoral immunity, cell-mediated immunity, and neutrophil function have been reported, although the pathogenetic significance of these findings remains an enigma.^{1991,2133-2136} Recent studies have concluded that T cells play an integral role in the development of pyoderma gangrenosum. They appear to be trafficking to the skin under the influence of an antigenic stimulus.²¹³⁷ IL-8, a potent chemotactic polypeptide for neutrophils, is increased in the serum and lesional fibroblasts in pyoderma gangrenosum.²¹³⁸ The role, if any, of a vasculitis in the pathogenesis of pyoderma gangrenosum is debatable (see later). Matrix metalloproteinases, mediators of tissue destruction in chronic wounds, are increased in pyoderma gangrenosum. This applies to MMP-9 and MMP-10.²¹³⁹ TNF- α was also increased in this study.²¹³⁹ The role of infection, probably as a secondary process leading to chronicity of lesions, has not been ruled out. *Chlamydia pneumoniae* has been cultured from a case of pyoderma gangrenosum.²¹⁴⁰

Systemic corticosteroids are the mainstay of treatment, but the side effects of chronic usage mean that other therapies are needed as adjuvants or replacements when corticosteroids are curtailed.^{2141,2142} Among other agents or methods that have been used are cyclosporine,^{2122,2143,2144} mycophenolate mofetil,²¹⁴⁵⁻²¹⁴⁷ thalidomide,^{2148,2149} clofazimine,²¹⁵⁰ mesalazine (when associated with ulcerative colitis),²¹⁵¹ IVIG,^{2141,2143} tacrolimus,^{2009,2152} adalimumab,²¹⁵³⁻²¹⁵⁶ alefacept,²¹⁵⁷ infliximab,^{2002,2158-2160} pimecrolimus 1% cream, intravenous²⁰⁰¹ or intralesional corticosteroids,²¹⁶¹ minocycline²¹⁶² negative pressure dressings,²¹⁶³ hyperbaric oxygen,²⁰³⁸ and anticoagulants when associated with prothrombotic dysfibrinogenemia²¹⁶⁴ or plasmapheresis.²¹⁶⁵

Histopathology^{1991,1992,2166}

The findings are quite variable and depend on the age of the lesion and the site biopsied. A review of 103 cases found that only 7% had biopsy findings suggestive of the disease; the conclusion of these authors was that tissue pathology should not be used to exclude a diagnosis of pyoderma gangrenosum.²¹⁶⁷ The most controversial aspect of the histopathology relates to the presence (or absence) of a vasculitis.²⁰⁷¹ A lymphocytic and/or leukocytoclastic vasculitis has been reported at the advancing erythematous edge in 73% of cases,¹⁹⁹³ although Ackerman has written, "I now believe that all cases of

Figure 8.39 Pyoderma gangrenosum, early lesion. There is per follicular inflammation with intradermal neutrophilic abscess formation. (H&E)

pyoderma gangrenosum begin as folliculitides and that vasculitis is not a primary event in pyoderma gangrenosum".²¹⁶⁸

The earliest lesion shows sterile follicular and perifollicular inflammation with intradermal abscess formation (**Fig. 8.39**).^{2017,2168,2169} Lesions of Sweet's syndrome are rarely follicular based.²¹⁷⁰ In later lesions, there is necrosis of the superficial dermis and epidermis forming an ulcer, the base of which shows a mixed inflammatory cell infiltrate with abscess formation.²¹⁶⁶ Undermining inflammation is a characteristic feature at the edge of the ulcer. The process may extend into the underlying subcutis (**Fig. 8.40**). Giant cells are sometimes present, particularly in cases associated with Crohn's disease.²¹⁷¹ Although there are numerous reports of leukemia-associated pyoderma gangrenosum, the finding of myeloblasts in the skin has rarely been described.²⁰³³

At the advancing edge, there is a tight perivascular infiltrate of lymphocytes and plasma cells with endothelial swelling and fibrinoid extravasation representing a lymphocytic vasculitis.²¹⁶⁶ This finding has been disputed by some authors.²¹²⁶ A leukocytoclastic vasculitis is sometimes present.^{2169,2172,2173} There is often subepidermal edema at the advancing edge. This is prominent and associated with intraepidermal bullae with pustulation in those variants with bullous changes at the advancing edge. There is a superficial resemblance to dermatitis herpetiformis in cases in which the neutrophils form a band-like infiltrate beneath the edematous zone. Acanthosis is a prominent change in the perilesional erythematous zone.

In the variant known as *superficial granulomatous pyoderma*, there are superficial dermal abscesses surrounded by a narrow zone of histiocytes and some giant cells of foreign body type.^{2046,2047,2049,2174} Necrotizing granulomas are rarely seen in other forms of pyoderma gangrenosum.²¹⁷⁵ Beyond the zone of histiocytes, there is a mixed inflammatory cell infiltrate that usually includes plasma cells and eosinophils. There is often pseudoepitheliomatous hyperplasia. The follicular infundibula may be enlarged, possibly in association with transepidermal elimination of inflammatory debris. There is some resemblance to the changes seen in blastomycosis-like pyoderma, although in this latter condition the inflammatory process is usually much deeper in the dermis and palisading histiocytes are not usually prominent; furthermore, the two processes usually occur at different sites.

It has been suggested that pyoderma gangrenosum has four distinctive clinical and histological variants – ulcerative, pustular, bullous, and

Figure 8.40 Pyoderma gangrenosum. A deep ulcer is present, as is tight lymphocytic cuffing of vessels in the margin of the ulcer. (H&E)

vegetative.²¹⁷⁶ In part, these ‘variants’ represent stages in the evolution of the lesions and, not surprisingly, overlap exists. The *ulcerative* lesions are said to be characterized by central neutrophilic abscesses and ‘peripheral lymphocytic angiocentric’ infiltrates (lymphocytic vasculitis?); the *pustular* lesions by subcorneal pustules with subepidermal edema and dense dermal neutrophilia; the *bullous* lesions by subepidermal bullae with dermal neutrophilia; and the *vegetative* form (previously reported from the same institution as superficial granulomatous pyoderma) by pseudoepitheliomatous hyperplasia, dermal abscesses, sinus tracts, and a palisading granulomatous reaction (**Fig. 8.41**).²¹⁷⁶

Immunoreactants have been reported around blood vessels in the dermis in more than 50% of cases of pyoderma gangrenosum in one series.²¹⁷⁷ They have not been detected by others.²¹²⁶

Differential diagnosis

Fully developed ulcerative lesions are difficult, if not impossible, to distinguish from ulcers due to a variety of causes – a widely experienced source of frustration for both clinician and pathologist. Convincing leukocytoclastic vasculitis not immediately beneath or adjacent to an ulcer is often difficult to identify in these specimens, at least in the author’s experience. The best chance for a specific diagnosis occurs in

Figure 8.41 Pyoderma gangrenosum, superficial granulomatous type. There is a dermal abscess that drains into an overlying follicle. (H&E)

early lesions, when neutrophilic folliculitis occurs in the context of a supportive clinical history. Superficial granulomatous pyoderma is fairly characteristic. Although it has some overlapping features with blastomycosis-like pyoderma, organized palisading granulomas are not a feature of the latter condition. Differentiating between pyoderma gangrenosum and necrotizing fasciitis can be a difficult task, but it is an important one because the clinical management of these two conditions is quite different.²¹⁷⁸ Regarding histopathologic features, necrotizing fasciitis often shows minimal epidermal change, dermal lymphohistiocytic inflammation, suppuration and necrosis of superficial fascia, thrombosis, and edema in fascial planes. Pyoderma gangrenosum beyond the primary stages tends to show subepidermal edema and undermining inflammation at the ulcer border, with extension of inflammation into the subcutis. Deep vessel thrombosis is not a characteristic feature of pyoderma gangrenosum; on the other hand, the presence of granulomas (as can be seen, for example, in pyoderma gangrenosum associated with Crohn’s disease or in the superficial granulomatous pyoderma variant) may be a feature arguing against necrotizing fasciitis. Negative blood and tissue culture studies would of course tend to favor pyoderma gangrenosum.

POLYMORPHIC LIGHT ERUPTION

In some cases of polymorphic light eruption, particularly the papulovesicular variant, the tight perivascular lymphocytic infiltrate mimics closely the picture seen in lymphocytic vasculitis, although there is never any fibrinoid change in the vessels. Red cell extravasation is invariably present in the papulovesicular variant. Polymorphic light eruption is discussed further on page 624.

TRAPS

TRAPS (OMIM 142680) is the acronym for tumor necrosis factor receptor-associated periodic syndrome, an autosomal dominant periodic fever syndrome (an autoinflammatory disease) resulting from mutations in the *TNFRSF1A* gene, which encodes the tumor necrosis factor receptor.⁹⁶⁸ It is on chromosome 12p13.3. Activation of the IL-1 β pathway is a common mechanism in the pathogenesis of the autoinflammatory diseases.

The skin eruption consists of migratory macules and patches and edematous urticarial plaques beginning in the first few years of life. The disease is more common in patients from northern European

backgrounds. Fever is always present, and there may be abdominal pain, myalgia, arthralgia, pleuritic chest pain, and headache.⁹⁶⁸ Amyloidosis is present in 10% of patients.⁹⁷¹ It must be distinguished from the other autoinflammatory diseases, including hyperimmunoglobulinemia D syndrome (see p. 239), familial Mediterranean fever (see p. 247), PAPA syndrome with its associated pyoderma gangrenosum (see p. 268), and the three cryopyrinopathies, one of which has been known for decades as Muckle–Wells syndrome.⁹⁷¹ Patients respond to high-dose corticosteroids, but their long-term use is limited. Recently, the IL-1 receptor antagonist anakinra was used successfully to treat a patient.⁹⁷¹

Histopathology

There is a superficial and deep perivascular and interstitial infiltrate of lymphocytes and monocytes. The photomicrographs in a large series of 25 patients suggest a lymphocytic vasculitis without fibrin.⁹⁶⁸ Cells expressing CD68, CD3, CD4, and CD8 are present in the infiltrate.⁹⁷¹ Neutrophils do not seem to be a component of the infiltrate.

LEUKEMIC VASCULITIS

A leukocytoclastic vasculitis may occur in patients with leukemia secondary to sepsis and medications or as a rare paraneoplastic phenomenon. A specific form of vasculitis, mediated by leukemic blast cells rather than reactive inflammatory cells, has been reported as leukemic vasculitis.^{2179–2181} It is a manifestation of leukemia cutis, particularly in the setting of acute myelomonocytic leukemia. Leukemic vasculitis is usually an indicator of poor prognosis.²¹⁸²

Atypical (angiocentric) infiltrates can also be seen in angiocentric lymphoma, its variant lymphomatoid granulomatosis, some cutaneous lymphomas of natural killer cells (CD56⁺), and in the reversible cutaneous lymphoma associated with methotrexate therapy for rheumatoid arthritis.²¹⁸³

VASCULITIS WITH GRANULOMATOSIS

The term ‘vasculitis with granulomatosis’ is the preferred designation for those diseases that show varying degrees of granulomatosis, both angiocentric and unrelated to vessels, in combination with a vasculitis that may be necrotizing.^{2184,2185} The term ‘granulomatous vasculitis’, although often used interchangeably, is more limited in its meaning²¹⁸⁶ and, strictly interpreted, refers to granulomatous involvement of vessel walls²¹⁸⁷ without the formation of extravascular granulomas.

The important clinical entities showing vasculitis with granulomatosis include Wegener’s granulomatosis, lymphomatoid granulomatosis, allergic granulomatosis (Churg–Strauss syndrome), and midline granuloma.²¹⁸⁴ Temporal arteritis and Takayasu’s arteritis are usually considered with this group, although the granulomatous inflammation is restricted to the vessel walls. Granulomatous involvement of vessel walls and/or perivascular granulomas may also be seen in a wide range of clinical settings that include lymphoma,^{2188–2190} angioimmunoblastic lymphadenopathy, sarcoidosis,²¹⁹¹ systemic vasculitis,²¹⁸⁸ Crohn’s disease,^{905,2192,2193} drug reactions,²¹⁹⁴ the use of cocaine,²¹⁹⁵ the site of previous herpes zoster^{2196–2198} or herpes simplex,²¹⁹⁹ rheumatoid arthritis, infectious granulomatous diseases such as tuberculosis and tertiary syphilis, and less well-defined circumstances.²²⁰⁰ The important entities are considered here.

WEGENER’S GRANULOMATOSIS

Wegener’s granulomatosis is a rare systemic disease with necrotizing vasculitis and granulomas involving the upper and lower respiratory

tracts, accompanied usually by a focal necrotizing glomerulitis.²²⁰¹ A vasculitis involving both arteries and veins may involve other organs, including the skin.²²⁰² The disease usually presents in the fourth and fifth decades of life with symptoms related to the upper respiratory tract, such as persistent rhinorrhea and sinus pain.^{2202,2203} Childhood cases are uncommon.^{2204–2206} There is a female predominance.²²⁰⁶ Other clinical features may include a cough, hemoptysis, otitis media, ocular signs, gingival hyperplasia (strawberry gingiva),²²⁰⁷ arthralgia, and constitutional symptoms.^{1088,2208,2209} Several cases have been associated with vasculitis of the temporal artery; only one was of giant cell type.²²¹⁰ An association with Crohn’s disease has also been reported.²²¹¹

Cutaneous manifestations occur in 30–50% of cases and may occasionally be the presenting complaint.^{2212–2214} In a study from the Mayo Clinic reported in 2007, cutaneous lesions were present in approximately 10% of the 766 patients with Wegener’s granulomatosis evaluated there between 1996 and 2004.²²⁰⁶ They often take the form of papulonecrotic lesions distributed symmetrically over the elbows, knees, and sometimes the buttocks. Other reported clinical lesions²²¹⁵ include purpura,²²⁰³ vesicular and urticarial eruptions, large ulcers resembling pyoderma gangrenosum,^{2216–2218} facial erythematous papules and plaques mimicking granulomatous rosacea,²²¹⁹ subcutaneous nodules, necrotizing granulomas in scars, and, in two cases,^{2220,2221} breast involvement. Sweet’s syndrome has been reported in a patient with Wegener’s granulomatosis and end-stage renal disease.²²²² Diffuse dermal angiomas has been reported in a patient with Wegener’s granulomatosis who developed a hemodialysis-related arteriovenous fistula.²²²³

An important clinical variant is the so-called ‘limited form’ in which pulmonary lesions predominate and a glomerulitis is absent.^{2224,2225} Cutaneous lesions are less frequent and may take the form of subcutaneous nodules, protracted ulcers,²²²⁶ or malignant pyoderma.²²²⁷ The limited form has a better prognosis. Another clinical variant, characterized by protracted mucosal and cutaneous lesions, is known as *protracted superficial Wegener’s granulomatosis*.^{2187,2228,2229}

The etiology and pathogenesis are unknown, but it appears to result from an immunological disturbance, possibly following an infective trigger.¹¹²⁷ A clinical response to antibiotics is sometimes demonstrated, although this does not necessarily imply an infective etiology.²²³⁰

Of interest is the finding in the serum of antibodies, usually of IgG class, that react against cytoplasmic components of neutrophils.²²³¹ Two types of these ANCA are found – c-ANCA, which are mostly directed against granular enzyme proteinase 3 (PR3), and p-ANCA, which have multiple antigenic specificities, the best defined being myeloperoxidase (MPO).^{1127,2044,2232–2235} In Wegener’s granulomatosis, approximately 80% of patients have ANCA, mostly of c-ANCA type.^{2217,2231,2236} In the study of 17 patients at the Mayo Clinic, all patients were c-ANCA/PR3-ANCA positive, although 1 patient was negative at presentation with cutaneous lesions but subsequently became positive.²²⁰⁶ The myeloperoxidase subtype of p-ANCA tends to occur in patients with renal-limited disease, but it is seen in some patients with Wegener’s granulomatosis; no patient has had both subtypes.^{845,2236} The titer of ANCA reflects disease activity.⁸⁴⁵

Another disease complex has been proposed – ANCA-associated systemic vasculitis.²²³⁷ It includes what is now known as Wegener’s granulomatosis as well as microscopic polyangiitis (polyarteritis) and renal-limited disease (crescentic glomerulonephritis).¹¹²⁷ ANCA-positive leukocytoclastic vasculitis may also occur. One such case was precipitated by thioridazine.²²³⁸ In these conditions, the pathogenesis may be an autoimmune inflammatory response, characterized by specific mediators, in which the endothelium is both target and active participant.⁷⁹⁹

Wegener’s granulomatosis is almost uniformly fatal if not treated; deaths may occur despite treatment. Oral corticosteroids given with cyclophosphamide are the treatment of choice.^{2207,2219} Tacrolimus,

topical or systemic, may be used in association with corticosteroids.²²³⁹ Rituximab has also been reported to be effective.²²⁴⁰

Histopathology^{2187,2212,2241,2242}

The full picture of a necrotizing vasculitis with granulomatosis is seen in the skin in 20% or less of cases of Wegener's granulomatosis.²¹⁸⁴ Sometimes the findings are quite nonspecific, with only a chronic inflammatory cell infiltrate in the dermis. The infiltrate is sometimes perifollicular and acneiform.²²⁰⁶ In specifically diagnostic lesions, vascular and extravascular changes are present in varying proportions.

Extravascular changes include small foci of necrosis and fibrinoid degeneration, usually without vascular participation. There may be some neutrophil infiltration and nuclear dusting in these foci. Rarely, the pattern mimics a neutrophilic dermatosis.²²⁴³ Palisading, which varies from minimal to well-defined, may develop in older lesions (Fig. 8.42A). Sometimes the pattern is that of a palisaded and neutrophilic dermatosis.²²⁰⁶ Poorly formed granulomas, unrelated to necrotic areas, may also be present. Giant cells are almost invariably present in the palisading margins of the granulomas, in granulation tissue lining

ulcerated surfaces, or scattered irregularly in the chronic inflammation that forms a background to the entire process.²¹⁸⁷ Rarely, eosinophils are prominent in the infiltrate.²²⁴⁴ No atypical mononuclear cells are present. Granulomas resembling those seen in allergic granulomatosis (Churg–Strauss syndrome) have been reported in several cases.^{2206,2245}

Vascular changes may take the form of a necrotizing angiitis involving small and medium-sized dermal vessels. Fibrin extends around the vessel walls, and sometimes there is a fibrin thrombus in the lumen (Fig. 8.42B). A small vessel leukocytoclastic vasculitis is sometimes present.²²⁴⁶ Red cell extravasation accompanies either type of vasculitis. Less commonly, a granulomatous vasculitis with angiocentric granulomas is present.²²¹² In a study of 46 patients, no examples of granulomatous vasculitis were found. Extravascular granulomatous inflammation was found in 19% of cases.²²⁴⁷ Patients with leukocytoclastic vasculitis (31%) had onset of the disease at an earlier age, and more rapidly progressive and widespread disease.²²⁴⁷ A case mimicking Wegener's granulomatosis has been reported following the prolonged use of cocaine. It was labeled as a pseudovasculitis in the absence of any true vascular involvement.²²⁴⁸ Eosinophilic angiocentric fibrosis, a disease of the upper airways, sometimes seen in association with granuloma faciale has been reported in association with Wegener's granulomatosis.²²⁴⁹

Special stains are noncontributory, although specific infective causes of granulomas should always be kept in mind in the differential diagnosis. Immunofluorescence microscopy will sometimes show C3 and immunoglobulins related to vessels in early lesions.

LYMPHOMATOID GRANULOMATOSIS

Lymphomatoid granulomatosis was first described in 1972²²⁵⁰ as a unique form of pulmonary angiitis and granulomatosis that frequently had extrapulmonary manifestations.²²⁵¹ It is now regarded as an angiocentric lymphoma (see p. 1199).^{2252–2254} Skin lesions have been noted in 40–60% of cases, and these may be the presenting complaint.^{2255–2260} They take the form of erythematous or violaceous nodules and plaques that may be widely distributed on the trunk and lower extremities.²²⁵⁶ Rarely, paranasal or ulcerated palatal lesions are present. A related process may also be seen in association with Epstein–Barr virus.²²⁶¹

Death may result from respiratory failure or the effects of the diffuse peripheral lymphoma that may develop.^{2262–2270} The histopathology of these cases was often angiocentric and angioinvasive (Fig. 8.43).

CHURG–STRAUSS SYNDROME

Churg–Strauss syndrome (allergic granulomatosis) is a clinically distinctive, idiopathic disease in which systemic vasculitis and hypereosinophilia develop in individuals with pre-existing asthma and allergic rhinitis.^{2271–2274} Tissue eosinophilia, peripheral neuropathy, cardiac lesions, oral ulceration,²²⁷⁵ and mild renal disease may also be present. The condition tends to occur in middle-aged individuals and predominates in men.²²⁷⁶ The American College of Rheumatology criteria require four of the following six features for the diagnosis of Churg–Strauss syndrome: asthma, eosinophilia greater than 10%, paranasal sinusitis, pulmonary infiltration, histological proof of vasculitis, and mononeuritis multiplex.²²⁷⁷ A prothrombotic state has been described, reflected in elevated levels of prothrombin fragment 1+2 and D-dimer.²²⁷⁸ There are also reports of more profound deep vein thrombotic complications; workups failed to reveal anticardiolipin antibodies, lupus anticoagulant, or abnormalities of protein C or S, antithrombin III, prothrombin gene mutation, or factor V Leiden mutation.²²⁷⁹ A limited form of the disease, in which not all of the previous features are present, has been described.²²⁸⁰ A case limited to the skin has also been reported.²²⁸¹ Rare associations include a temporal arteritis of non-giant cell type,²²⁸² purpura fulminans,²²⁸³ Wells' syndrome,^{2284,2285} and

Figure 8.42 Wegener's granulomatosis. (A) This is a palisading extravascular granuloma with a central focus of fibrinoid degeneration and some infiltration by neutrophils. (H&E) (B) There is a necrotizing vasculitis, with partial thrombosis and leukocytoclasia. (H&E)

Figure 8.43 (A) Lymphomatoid granulomatosis. (B) An atypical infiltrate involves the wall of a small artery in the deep dermis from this same case. (H&E)

the presence of antiphospholipid antibodies.²²⁸⁶ Cases have followed the use of leukotriene receptor antagonists for the treatment of asthma.^{2277,2287,2288}

Cutaneous lesions are common, occurring at some point in the disease in 40–81% of patients and as the presenting finding in approximately 14%.²²⁸⁹ These include purpura, erythema or urticarial plaques, and distinctive nodules.^{2290,2291} These nodules, which are often tender, arise on the scalp or symmetrically on the extremities.²²⁹² They may involve the dermis or subcutis. Ulceration may occur secondary to the arteritis and thrombosis of dermal vessels.²²⁹³ Bullous lesions have been rarely reported,²²⁹⁴ and there is a case of Churg–Strauss lesions developing in surgical scars.²²⁹⁵

The etiology of Churg–Strauss syndrome is unknown. Whether it is best categorized as an allergic disorder or a vascular disease is unclear.²²⁹³ Antibodies to hepatitis B virus and to the human immunodeficiency virus have been reported in only one case.²²⁹⁶ Antibodies to p-ANCA are often present.^{2277,2293} It has been suggested that these antibodies promote neutrophil sticking to vessel walls, initiating the vasculitis. Cytokine abnormalities (increased IFN- α , IL-2, TNF- α , IL-5, and IL-1 β) have also been reported.²²⁸⁶ Requena and colleagues believe that degeneration of collagen bundles, resulting from lysosomal

enzymes released from granulocytes, is the primary event. This is followed by the infiltration of histiocytes that become arranged in a palisade.²²⁹⁷

The prognosis is variable, but most patients appear to have a good response to corticosteroid therapy. In one case, a patient receiving corticosteroid therapy had complete resolution of skin lesions with the addition of dapsone; renal and sinus disease persisted, however, but were controlled with the substitution of cyclophosphamide.²²⁹⁸

Histopathology

The three major histological features are a necrotizing vasculitis, tissue infiltration by eosinophils, and extravascular granulomas.²²⁷² The vasculitis involves small arteries and veins, but it may also affect larger arteries and resemble polyarteritis nodosa. It may take the form of a leukocytoclastic vasculitis.^{2299,2300} Older lesions show healing with scarring. The tissue infiltration with eosinophils is accompanied by destruction of some of these cells, leading to release of their granules and increased eosinophilia of the collagen (Fig. 8.44A).²²⁷² The extravascular granulomas, which result in the cutaneous nodules found in some patients, show central necrosis that may be fibrinoid or partly

Figure 8.44 Allergic granulomatosis. (A) A flame figure is present in an area of numerous eosinophils. There is prominent subepidermal edema. (H&E) (B) An extravascular granuloma with central necrosis can be seen (delineated by arrows). The surrounding dermal infiltrate contains lymphocytes and eosinophils. (H&E)

basophilic, with interspersed eosinophils, some neutrophils, and also debris (Fig. 8.44B).²²⁹⁰ This area is surrounded by a granulomatous proliferation of histiocytes, lymphocytes, and giant cells, often in palisaded array.²²⁹⁰ Granulomas were present in less than half the autopsy cases included in one review.²²⁷² Non-necrotizing granulomas were present in a case of limited allergic granulomatosis.²²⁸⁰ A granulomatous vasculitis, as seen in other organs, may sometimes be present in cutaneous lesions of Churg–Strauss syndrome.²³⁰¹

In a review of the literature, among Churg–Strauss cases in which the cutaneous findings were reported in detail, it was found that the most common features were papulonodular lesions, with microscopic changes of extravascular Churg–Strauss granulomas, followed by lower extremity purpuric to necrotic lesions, featuring small vessel vasculitis with an eosinophil component; urticarial lesions and livedo reticularis were less common.²²⁸⁹ In one case presenting as urticarial papules and plaques, the microscopic changes were those of an interstitial granulomatous dermatitis with a prominent eosinophil component.²²⁸⁹ Hemorrhagic vesicular lesions show small vessel eosinophilic vasculitis with underlying eosinophilic and granulomatous phlebitis, whereas pemphigoid-like bullae feature subepidermal separation and the image of a widespread interstitial granulomatous dermatitis with eosinophils.²²⁹⁴ In the lesions that developed in scars, there was a perivascular and palisading granulomatous infiltrate with leukocytoclasia that included both neutrophils and eosinophils.²²⁹⁵ Note that the three components mentioned previously do not always coexist temporally or spatially.²²⁷² Furthermore, similar extravascular granulomas, initially referred to as Churg–Strauss granulomas, have been described in association with circulating immune complexes.^{2245,2302–2305} These associated conditions include SLE, rheumatoid arthritis, Wegener’s granulomatosis, polyarteritis nodosa, Takayasu’s aortitis,²³⁰⁶ various lymphoproliferative disorders,²³⁰⁷ and some other conditions.^{2308,2309} Other terms used for these unique, palisaded granulomatous lesions include ‘rheumatoid papules’, ‘superficial ulcerating rheumatoid necrobiosis’, ‘interstitial granulomatous dermatitis with arthritis’, and, recently, ‘palisaded neutrophilic and granulomatous dermatitis of immune complex disease’.²³⁰² The term ‘interstitial granulomatous dermatitis’ is used here (see p. 214). The lesions present as papules, linear cords, or plaques on the trunk or extremities. In the granulomas found in these circumstances, the central necrotic area is invariably basophilic.²³¹⁰ Furthermore, there is an absence of the tissue eosinophilia within and around the granulomas that is seen in Churg–Strauss syndrome. These eosinophils, in addition to the neutrophils, may have a pathogenic role in this disease.²³¹¹

Differential diagnosis

The microscopic image of Churg–Strauss lesions can be quite unique and should certainly be suggested by the combination of necrotizing vasculitis and numerous eosinophils. However, as noted previously, more than a few eosinophils can sometimes be found in *vasculitis due to other causes*. Churg–Strauss granulomas can be identified occasionally in non-Churg–Strauss conditions. One of these, mentioned previously, is *Wegener’s granulomatosis*. Others include *connective tissue diseases* (*lupus erythematosus*, *rheumatoid arthritis*), *polyarteritis nodosa*, and *lymphoma*. Careful evaluation of accompanying microscopic changes and the clinical and laboratory findings may be necessary to exclude these other diseases. Churg–Strauss lesions with changes of interstitial granulomatous dermatitis can closely resemble the variants bearing that name associated with other systemic diseases (often connective tissue diseases) or with drugs – particularly the latter because eosinophils are frequently present. However, the non-Churg–Strauss forms of interstitial granulomatous dermatitis have a predominance of neutrophils, and at least some examples of drug-induced interstitial granulomatous dermatitis feature vacuolar alteration of the epidermal basilar layer.

LETHAL MIDLINE GRANULOMA

Lethal midline granuloma (Stewart type of nonhealing necrotizing granuloma) is a controversial disease category, now of historical interest only, that was regarded by some as a distinct clinicopathological entity²³¹² and by others as merely a clinical term to describe any rapidly evolving, destructive lesion of the nose and deep facial tissues.^{2313,2314} This term has now been discarded, and the condition subsumed under the category Extranodal NK/T-Cell Lymphoma, Nasal Type (see Chapter 41).²³¹⁵ EBV had been detected in many cases.^{2269,2316}

Histopathology²³¹⁰

Lethal midline granuloma, as originally defined, could be included here because granulomas and vasculitis sometimes occurred.²¹⁸⁴ The usual picture was of a dense polymorphic infiltrate composed of lymphocytes, plasma cells, and some polygonal and spindle-shaped histiocytes in a background of granulation and fibrous tissue. Necrosis was usually prominent. Vasculitis was uncommon, but endarteritis obliterans was often seen. Clear-cut granulomas were present in 4 of 10 cases in one series.²³¹²

GIANT CELL (TEMPORAL) ARTERITIS

Giant cell arteritis is a granulomatous vasculitis involving large or medium-sized elastic arteries, with a predilection for the superficial temporal and ophthalmic arteries and, to a lesser extent, other extracranial branches of the carotid arteries.^{2317–2320} Occasionally, both temporal arteries are involved, although pain may be bilateral in the absence of proven involvement of both vessels.²³²¹ The onset is usually late in life. The protean clinical manifestations include severe headache, jaw claudication, and visual and neurological disturbances.²³²² Its relationship to polymyalgia rheumatica is controversial.

Cutaneous manifestations are uncommon, the most frequent being necrosis of the scalp with ulceration.^{2323–2329} This may be localized to one side or bitemporal with large areas of necrosis.²³³⁰ Actinic granuloma is a rare association.^{2331,2332} Alopecia, hyperpigmentation, and scalp tenderness may occur.²³³³ Giant cell arteritis is rarely associated with other forms of systemic vasculitis.²³³⁴

The etiology is unknown. It has been suggested that the condition results from inflammation and elastolysis (with resorption), involving actinically damaged fibers of the internal elastic lamina of the temporal artery.²³³⁵ Another suggestion is that cell-mediated immunity, especially a T-cell-regulated granulomatous reaction, may play a role in the pathogenesis of temporal arteritis.²³³⁶ The antigen in such cases may be actinically degenerate elastic tissue in the vessel wall.²³³⁷ Another theory involves reactivation of latent herpes simplex virus, a major repository being the trigeminal ganglia that provide the temporal arteries with a proportion of their innervation. A study of 39 consecutive temporal artery biopsies performed for suspected temporal arteritis revealed HSV DNA in 21 of 24 histologically positive cases and in 8 of 15 histologically negative lesions.²³³⁸

The rare form of temporal arteritis that occurs in children and young adults is not the same as classic giant cell (temporal) arteritis. In 2002, Watanabe *et al.* suggested that it was a manifestation of Kimura's disease based on a case in an elderly patient with Kimura's disease who subsequently developed typical features of juvenile temporal arteritis.²³³⁹ It presents as a lump on the forehead that may be nontender or painful.²³⁴⁰ The erythrocyte sedimentation rate is normal, in contrast to the usually elevated rate in the giant cell form.^{2340–2342} A similar case, but with accompanying systemic vasculitis, has been reported in an adult.²³⁴³

Systemic corticosteroids are the treatment of choice. As symptoms subside, the dose should be gradually tapered. Usually, a small

maintenance dose is continued for 1 or 2 years to avoid relapses.²³²⁸ To lessen the risk of blindness, the introduction of therapy should not be delayed.

Histopathology²³⁴⁴

It has been suggested that because a significant number of patients with clinical temporal arteritis have negative biopsies, a trial of corticosteroid therapy would be a better indicator of this diagnosis than temporal artery biopsy.²³⁴⁵ A recent study indicates that temporal artery biopsies do not affect management in the majority of patients suspected of having temporal arteritis, and they may be of benefit only in cases in which there is an American College of Rheumatology criteria score of 2 or 3 without biopsy (which is one of the five listed criteria).²³⁴⁶ Corticosteroid therapy is not without risk, however. The percentage of positive biopsies depends on the number of sections examined because skip lesions do occur.²³⁴⁷ In a recent retrospective study, the incidence of skip lesions was 8.5%, although a previous study recorded skip lesions in 28.3% of cases.²³⁴⁸ Another study examined further levels on 132 biopsies initially reported as normal and found one additional case of temporal arteritis, whereas 2 of 14 cases diagnosed initially as periarterial lymphocytic infiltration (see later) revealed giant cell arteritis on further levels.²³⁴⁹

The classic findings are a granulomatous arteritis involving the inner media, with prominent giant cells of both Langhans and 'foreign body' type (Figs. 8.45 and 8.46). This is associated with fragmentation and focal destruction of the internal elastic lamina, best seen on Verhoeff–van Gieson staining. However, disruption and reduplication of the internal elastic lamina has also been seen in approximately two-thirds of negative biopsies, suggesting that in most cases an elastic tissue stain does not contribute to the diagnosis of temporal arteritis and should probably be used only as a supplemental test in selected cases.²³⁵⁰ A non-specific inflammatory cell infiltrate that includes variable numbers of lymphocytes, histiocytes, and even eosinophils is often present. Giant cells are not mandatory for the diagnosis.²³⁵¹ They were present in 76 of 92 biopsies in one study.²³⁵² Their presence was associated with an increased incidence of polymyalgia rheumatica and blindness.²³⁵² Granulomatous inflammation may persist despite prolonged corticosteroid treatment and clinical resolution of the symptoms.²³⁵³ According to one study, temporal small vessel inflammation appears to commonly accompany positive temporal artery biopsies but can also occur as an isolated finding; patients who have isolated temporal small vessel

Figure 8.45 Temporal arteritis. An inflammatory cell infiltrate is present in relation to the internal elastic lamina. (H&E)

Figure 8.46 Temporal arteritis. A few multinucleate giant cells and some lymphocytes are present in the wall of the temporal artery adjacent to the internal elastic lamina. (H&E)

inflammation more often have symptoms of polymyalgia rheumatica.²³⁵⁴ A patient with end-stage renal disease who presented with blurring of vision was found to have calciphylaxis of the temporal artery (along with similar changes in vessels in the legs). The authors of this report note that calcification involved the internal elastic lamina and media, whereas typical atherosclerotic changes mainly affect the media of the artery.²³⁵⁵

Corcoran *et al.* attempted to assess the significance of small foci of perivascular inflammation without any intimal or medial involvement (**periarterial lymphocytic infiltration**). The authors concluded that although this change may be a marker of associated vasculitis in a small number of cases (discussed previously), in the majority of cases it had no significance.²³⁵⁶ It may be an age-related change.

Some biopsies show intimal thickening with a proliferation of fibroblasts and myointimal cells but little or no change in the media.²³⁴⁴ There is usually an abundant myxomatoid stroma and a scattering of inflammatory cells. The internal elastic lamina is fragmented or thickened, with some loss of staining with elastic stains. The lumen is narrowed. These changes appear to represent an active process and not a healed stage, as once thought.²³⁴⁴ If there is no inflammation at all, however, reliable distinction from arteriosclerotic changes is impossible.²³⁵⁷ In old lesions, there may be evidence of recanalization of the lumen.

A much more florid inflammatory reaction is present in the exceedingly rare cases of Buerger's disease (thromboangiitis obliterans) of the temporal artery.²³⁵⁸

In juvenile temporal arteritis, there is an eosinophilic panarteritis and thrombosis, with or without microaneurysmal disruption of the artery. Lymphocytes and plasma cells are also present, but there are no giant cells.^{2340,2342} Biopsy from one case of juvenile temporal arteritis showed intimal thickening, disruption of the internal and external elastic laminae, and numerous eosinophils in the vessel intima, together with changes around the vessel (lymphoid follicles, eosinophilic infiltrates, and capillary proliferation) resembling those of Kimura's disease.²³⁵⁹

TAKAYASU'S ARTERITIS

Takayasu's arteritis (aortic arch syndrome, pulseless disease) is an uncommon large vessel granulomatous vasculitis with a predilection for young females.²³⁶⁰ It results in fibrosis, leading to constriction or

occlusion of the aorta and its main branches. Associated skin lesions include erythema nodosum, pyodermatous ulcers, nonspecific erythematous rashes, urticaria, and necrotizing vasculitis involving small blood vessels of the skin.^{2306,2360,2361}

Approximately 50% of patients respond to corticosteroids. Of those who do not, a further 50% respond to methotrexate.²³⁶² The remainder do not respond to current treatments available.²³⁶²

MISCELLANEOUS VASCULAR DISORDERS

Several vascular disorders do not fit into any of the other major categories. One example is collagenous vasculopathy in which there is generalized telangiectasia with thick collagen deposits around the basal lamina resembling amyloid (see below).²³⁶³ Another example, which is not considered further, is the development of stasis dermatitis of the hand secondary to an iatrogenic arteriovenous fistula.²³⁶⁴ Another consequence of fistulas is the **vascular steal syndrome**, in which ischemic manifestations, including gangrene requiring amputation, develop distal to the fistula.^{2365,2366} Some of these conditions are mentioned in other sections; they are included here for completeness.

CAPILLARY LEAK SYNDROME

The capillary leak syndrome is a rare, potentially life-threatening condition caused by a shift of intravascular fluid and proteins into the interstitial space, with subsequent hypovolemic shock.²³⁶⁷ Muscle edema may initiate rhabdomyolysis. There is localized or diffuse skin edema.²³⁶⁷ Three forms are recognized:

1. Idiopathic
2. Cases associated with cutaneous diseases such as pustular psoriasis, Ofuji's papuloerythroderma, and leukemias
3. Drug-induced cases, associated with docetaxel, gemcitabine, acitretin,^{2367,2368} sirolimus, G-CSF, IL-2, or anti-CD22 antibodies.

The pathogenesis is unknown, but it probably follows increased vascular permeability resulting from cytokine damage to the endothelium.

Treatment consists of withdrawal of any potential drug cause and the use of systemic corticosteroids.²³⁶⁷

VASCULAR CALCIFICATION

Calcification of the media of muscular arteries is a well-known complication of the aging process (Mönckeberg's sclerosis). It may also occur in cutaneous and deeper vessels in chronic renal failure, affecting predominantly small arteries. In these circumstances, the calcification may be accompanied by intimal hyperplasia, vascular thrombosis, and cutaneous ulceration and necrosis.^{284-286,2369-2371} There is usually an elevated calcium-phosphate product and secondary hyperparathyroidism.²³⁷² The term 'calciphylaxis' has been used for this process, although it has also been used for a subgroup of patients with renal failure with vascular and soft tissue calcification without an elevated calcium-phosphate product (see p. 425).²⁸⁵ Calciphylaxis has been reported in patients without renal failure.²³⁷³

Histopathology

The calcification involves the media of small arteries in the lower dermis and subcutis. It is often circumferential and accompanied by intimal fibrosis and thickening. Superimposed thrombi may be present, and recanalization may subsequently occur.

COLLAGENOUS VASCULOPATHY

Collagenous vasculopathy is an idiopathic microangiopathy involving the superficial blood vessels of the skin.²³⁷⁴ It presents with asymptomatic telangiectasias involving predominantly the trunk and proximal extremities. Only a few cases have been reported.^{2363,2374}

Histopathology

There are ectatic superficial small blood vessels with laminated hyalinized perivascular deposits of type IV collagen. They are highlighted with the PAS stain, after diastase digestion.²³⁷⁴

PERICAPILLARY FIBRIN CUFFS

Fibrin cuffs are a common finding around capillary blood vessels in venous leg ulcers. Initially, they were thought to be of pathogenetic significance in the formation of the ulcer and the accompanying lipodermatosclerosis.²³⁷⁵ Incidentally, it is now thought that leukocyte binding to endothelial cells, as a result of their expression of adhesion molecules, contributes to the pathogenesis of venous ulcers.²³⁷⁶ Recent studies have shown pericapillary fibrin cuffs (caps) in leg ulcers of nonvenous origin and adjacent to ulcers.^{2377,2378} They can also be seen in association with venous stasis without ulceration and in venous hypertension of the hand caused by hemodialysis shunts.²³⁷⁹ This indicates a role for venous hypertension in their pathogenesis.

VASCULAR ANEURYSMS

Pulsatile cutaneous aneurysms have been reported in several patients with arterial fibromuscular dysplasia.²³⁸⁰

A large vessel, which may at first glance appear to be aneurysmal, is also seen in the condition known as caliber-persistent artery (see p. 1077).

Traumatic aneurysms/pseudoaneurysms of the superficial temporal artery are a neglected entity. A report of two cases in 2003 stated that of the 386 facial aneurysms reported to that time, 327 involved the superficial temporal artery.²³⁸¹ Its exposed position overlying the frontal bone makes it susceptible to trauma. It may present as a cyst or lipoma.²³⁸¹

ERYTHRMALGIA

Erythrmalgia and erythrmalgia both refer to a symptom complex characterized by recurrent, red, warm extremities accompanied by burning pain,^{2382–2384} which lasts for minutes to days. The attacks may be precipitated by warmth, exercise, or limb dependency.²³⁸⁴ Michiels and colleagues defined erythrmalgia as the symptom complex that accompanies thrombocythemia, and they defined erythrmalgia as an independent disease process that may arise at a young age (primary erythrmalgia) or be associated with various underlying disorders (but not thrombocythemia) in adults (secondary erythrmalgia).^{141,142,2385,2386}

Primary erythrmalgia (OMIM 133020) is an autosomal dominant disorder due to a mutation in the *SCN9A* gene on chromosome 2q24.²³⁸⁷ It encodes a voltage-gated sodium channel that is predominantly expressed in sensory and sympathetic neurons. Linkage to chromosome 2q has been excluded in another family, suggesting genetic heterogeneity.²³⁸⁸ A low mutation rate in the *SCN9A* gene has also been found in a study, but no mutations were found in two other sodium channel genes, *SCN10A* and *SCN11A*.²³⁸⁹

Erythrmalgia may be broader than the definition proposed previously.^{2390,2391} The final common pathway may be microvascular arteriovenous shunting,²³⁹² although small-fiber neuropathy has been suggested

as another contributing factor.^{2393,2394} Uncommonly, it may coexist with Raynaud's phenomenon – two seemingly opposite conditions.^{2395,2396} It has also coexisted with perniosis, another temperature-related vascular syndrome.²³⁹⁷ It has been reported as a paraneoplastic phenomenon,²³⁹⁸ usually associated with myelodysplastic syndrome,²³⁸⁴ and following the use of ticlopidine, an inhibitor of platelet aggregation,²³⁹⁹ verapamil, and bromocriptine.²⁴⁰⁰ It has also been reported in a patient with HIV infection.²⁴⁰¹ Thermoregulatory sweat testing, which is a sensitive and useful marker of small-fiber neuropathy, can be used to confirm the diagnosis because small-fiber neuropathy is prevalent in this condition.²⁴⁰² The anhidrosis may be global or distal in location.²⁴⁰²

Patients with erythrmalgia often soak their feet in ice water to alleviate the pain. Aspirin may be effective in patients with an underlying myeloproliferative disorder. For idiopathic cases, serotonin reuptake inhibitors such as venlafaxine may benefit patients.²⁴⁰³

Histopathology

Recent studies of primary erythrmalgia have shown thickening of the basement membrane of capillaries, moderate endothelial swelling, perivascular edema, and a scant perivascular infiltrate of mononuclear cells.¹⁴¹ Smooth muscle hyperplasia of arteriolar walls may be present.²⁴⁰⁰ There is usually mild dilatation of capillaries in the superficial dermis. There may be mild dermal fibrosis. A relative decrease in small nerve fiber density is often present.²⁴⁰⁰ In cases secondary to myeloproliferative disorders, small vessel thrombi are often present.

CUTANEOUS NECROSIS AND ULCERATION

There are many causes of cutaneous necrosis, most of which were discussed in the section on vascular occlusive diseases at the beginning of this chapter. Additional causes include severe vasculitis;⁷²¹ septic vasculitis; angiotropic lymphoma; calciphylaxis;²³⁷⁰ oxalosis; thromboemboli; some arthropod bites, including wasp stings; and certain drugs and injections, such as cisplatin in systemic scleroderma,²⁴⁰⁴ norepinephrine (noradrenaline) and dopamine in cardiogenic shock,²⁴⁰⁵ triple vaccine (DTP) injection,²⁴⁰⁶ levamisole,²⁴⁰⁷ and recombinant interferon.^{2408–2410} Scalp necrosis has followed the local injection of heroin;²⁴¹¹ methadone and other injections have caused ulceration at other sites.^{2412,2413} It has been reported as a paraneoplastic phenomenon, the *paraneoplastic acral vascular syndrome*, an example being the occurrence of digital necrosis associated with ovarian cancer;²⁴¹⁴ there are many other examples and causes.²⁴¹⁵ Some of the most striking examples are seen in association with purpura fulminans. Intrauterine epidermal necrosis is an exceedingly rare condition in which the infant dies soon after birth. There is full-thickness epidermal necrosis with calcification in the skin and appendages.²⁴¹⁶

Numerous cases of ulceration have been reported in the past few years due to nicorandil, a vasodilator used to control angina.^{2417–2419} The mechanism of these ulcers remains unknown, but it is thought to involve the toxicity of the drug or its metabolites as well as the vascular steal phenomenon in vulnerable sites such as peristomal²⁴²⁰ and perianal regions.^{2421–2425} Other sites involved include oral and vaginal mucosa and penile skin.²⁴²⁶

Chronic ulcers, particularly on the legs, are frequently biopsied, often to exclude malignancy. It is sometimes difficult to offer an etiological diagnosis because of the superficial nature of the biopsy material. The common causes of chronic leg ulcers are venous and/or arterial insufficiency and neuropathic factors.²⁴²⁷ The *trigeminal trophic syndrome* is a specific example of neuropathic ulceration that follows damage to the trigeminal nerve.^{2428–2432} Despite the presence of small vessel disease in diabetics, it is stated that 70% of diabetic foot ulcers have adequate vascularity and are neuropathic in nature.²⁴³³ Ulcers mimicking pyoderma gangrenosum can occur at the site of injection of pentazocine.²⁴³⁴

Of leg ulcers in general, 10% are thought to be due to arterial insufficiency and a further 10% to combined arterial and venous disease.²⁴³⁵ Such ulcers will not usually heal with conservative measures.²⁴³⁵ Approximately 70% of chronic leg ulcers are attributed to chronic venous insufficiency.²⁴³⁴ Chronic ulcers are ones that do not heal within 6 weeks.²⁴³⁶ They are a significant cause of morbidity in the elderly.²⁴³⁷ In approximately 50% of patients with leg ulcers, there is a history of previous deep vein thrombosis (DVT).²⁸⁴ The DVT may be a consequence of protein S deficiency,²⁴³⁸ the antiphospholipid syndrome, or factor V Leiden mutation.^{248,250-252} The risk of a previous DVT being followed by a chronic leg ulcer is approximately 5%.²⁴⁸ In addition, many patients with chronic venous ulcers are overweight. Infection, blunt trauma, associated leg edema, penetrating injury, scratching, and contact dermatitis can all precipitate frank ulceration in venous insufficiency.²⁴³⁹ Venous ulcers usually show neovascularization of the upper dermis beneath the ulcer base, as well as hemosiderin pigment and mild fibrosis.

Other causes of leg ulcers include atrophie blanche, vasculitis,²⁴⁴⁰ prolidase deficiency, Klinefelter's syndrome,²⁴⁴¹ hyper-IgM syndrome,²⁴⁴² sickle cell disease,²⁴⁴³ hereditary spherocytosis,²⁴⁴⁴ hydroxyurea therapy,²⁴⁴⁵⁻²⁴⁴⁹ methotrexate therapy,²⁴⁵⁰ and thrombocytosis.¹³⁷ Hydroxyurea-induced leg ulcers have been treated with the local application of a sponge prepared from bovine collagen and oxidized regenerated cellulose (Promogran®).²⁴⁵¹ This material is a matrix metalloproteinase modulator. Decubitus ulcers are considered elsewhere (see p. 612).

Experimentally, venous leg ulcers have increased plasminogen activation. This influences the activity of MMP-2, which appears to play a role in their pathogenesis.²⁴⁵² There is also a persistence of MMP-9 in chronic wounds.²⁴⁵³ Trauma is sometimes an initiating event. If ulcers are treated with laboratory-cultured skin products, then the site often shows mucin deposition, myofibroblastic proliferation, and foreign body giant cells in up to 25% of cases. The presence of granulomas does not result in an adverse outcome.²⁴⁵⁴ A protective association has been found for β -adrenergic receptor agents (agonists and possibly also antagonists) and venous leg ulcers.²⁴⁵⁵

The treatment of venous ulcers involves wound care with debridement and avoidance of secondary infection, and management of the venous hypertension by elevation of the leg and/or compression therapy.²⁴⁵⁶ Useful therapeutic procedures include the use of compressive bandages, bandages impregnated with zinc oxide (Unna boot), pentoxifylline as an adjunct to compression bandaging,²⁴⁵⁶ cultured keratinocytes and tissue-engineered skin,²⁴⁵⁷ graded compression stockings,²⁴⁵⁶ and avoidance of contact sensitizers.²⁴⁵⁸ There is an excellent review article on wound management.²⁴⁵⁹

Harlequin ichthyosis	290	Palmoplantar keratoderma with sclerodactyly (Huriez syndrome)	295	Acrokeratosis verruciformis	314
Follicular ichthyosis	290	Punctate palmoplantar keratoderma	295	Xeroderma pigmentosum	315
Acquired ichthyosis	290	Striate palmoplantar keratoderma	295	Ectodermal dysplasias	316
Refsum's disease	291	Circumscribed keratoderma	295	Anhidrotic (hypohidrotic) ectodermal dysplasia	316
Other ichthyosis-related syndromes	291	Acquired keratoderma	296	Ectodermal dysplasia/skin fragility syndrome	317
Sjögren–Larsson syndrome	291	Aquagenic acrokeratoderma	296	Hidrotic ectodermal dysplasia	317
'KID' syndrome	291	Interdigital keratoderma	296	Orofaciodigital syndrome	317
Conradi–Hünermann–Happle syndrome	292	Oculocutaneous tyrosinosis	297	Cardiofaciocutaneous (CFC) syndrome	317
Neu–Laxova syndrome	292	Acrokeratoelastoidosis	298	Ectodermal dysplasias with clefting	317
'CHILD' syndrome	292	Pachyonychia congenita	298	Cutaneous and mucosal dyskeratosis	318
'IBIDS' (ichthyosis with trichothiodystrophy)	292	Cornoid lamellation	299	Nevoid hyperkeratosis of the nipple	318
'ILVASC'	292	Porokeratosis and variants	299	Peeling skin syndrome	318
Multiple sulfatase deficiency	292	Epidermolytic hyperkeratosis	301	Miscellaneous disorders	319
'MAUIE' syndrome	292	Epidermolytic acanthoma	302	Granular parakeratosis	319
Neutral lipid storage disease (Dorfman–Chanarin syndrome)	292	Acantholytic dyskeratosis	302	Circumscribed acral hypokeratosis	319
Shwachman syndrome	293	Focal acantholytic dyskeratosis	304	White sponge nevus	320
Palmoplantar keratodermas and related conditions	293	Acantholytic subset	304		
Palmoplantar keratodermas	293	Dyskeratotic subset	304		
Unna–Thost syndrome	293	Darier's disease	304		
Greither's syndrome	293	Galli–Galli disease	306		
		Grover's disease	306		

INTRODUCTION

This chapter deals with a heterogeneous group of diseases in which an abnormality of maturation, of keratinization, or of structural integrity of the epidermis is present. Many advances have been made in the past decade in our understanding of the molecular basis of these disorders. Most of these conditions are genetically determined, although a few are acquired diseases of adult life. An understanding of these disorders requires a knowledge of the structure of the epidermis and the process of normal keratinization.

Structure of the epidermis

The epidermis is a stratified squamous epithelial sheet covering the external surface of the body. It is composed of keratinocytes and melanocytes forming a binary system.¹ The keratinocytes are continuously regenerating with the cells undergoing terminal differentiation and death. Folds of the epidermis (the *rete ridges*) extend into the dermis while the dermis projects upwards between these ridges, the so-called '*dermal papillae*'. The epidermis is separated from the dermis by the basement membrane – a complex, multilayered structure that contributes to the structural framework of the epidermis (see p. 155).

Resting on the basement membrane is the *basal layer* of the epidermis, which contains the proliferating cells of the epidermis. Normally, only approximately 17% of the basal cells make up the dividing cell population. Cells leave this layer to undergo terminal differentiation, whereas some immediately die by apoptosis as a result of an intrinsic program or imbalance of signaling factors.² Cells destined to differentiate enter the *prickle cell layer*, where they acquire more cytoplasm and well-formed bundles of keratin intermediate filaments (tonofilaments). The major function of the keratin filaments is to endow epithelial cells with the mechanical resilience they need to withstand stress.³ The intercellular attachments, the prickles or *desmosomes*, develop here. There is also a change in the keratin composition of the keratin intermediate filaments; the keratins K1 and K10 are expressed in suprabasal cells, in contrast to K5 and K14 in the basal layer (see later). The prickle cell layer varies in thickness from 4 to 10 cells. As the cells are pushed outwards, they begin synthesizing the proteins that eventually constitute the keratohyaline granules and cell envelope of the granular layer and stratum corneum, respectively. The *granular layer* or *stratum granulosum* is identified by the presence of the keratohyaline granules. This layer is 1–3 cells thick. The cells lose their cytoplasmic organelles and metabolic activity. They flatten further and become compacted into a dense keratinous layer known as the *stratum corneum*. The superficial flake-like squames are eventually cast off (desquamate).

The total epidermal renewal time is approximately 2 months. The cells take 26–42 days to transit from the basal layer to the granular layer and a further 14 days to pass through the keratin layer.

Keratinization

Keratinization refers to the cytoplasmic events that occur in the cytoplasm of epidermal keratinocytes during their terminal differentiation. It involves the formation of keratin polypeptides and their polymerization into keratin intermediate filaments (tonofilaments). It is estimated that each keratin intermediate filament contains 20,000–30,000 keratin polypeptides. More than 30 different keratins have been identified – more than 20 epithelial keratins and 10 hair keratins.^{4,5} The epithelial keratins are divided by molecular weight and isoelectric points into two types – type I keratins, which are acidic and of lower molecular weight, and type II keratins, which are neutral basic. The type I keratins are further subdivided numerically from K10 to K20 and the type II keratins from K1 to K9. As a general rule, the epithelial

Table 9.1 Cellular location of the various keratins

Keratin type	Primary location
K1, K10	Suprabasal cells
K1b (now K77)	Eccrine sweat glands
K2e	Late suprabasal cells
K2p (now K76)	Hard palate
K3, K12	Cornea
K4, K13	Mucosa
K5, K14	Basal keratinocytes
K6a, K16	Palmoplantar, mucosa, appendages
K7	Myoepithelia, simple epithelia
K8, K18	Simple epithelia
K9	Palmoplantar
K11	Polymorphic variant of K10
K15	Basal keratinocytes, outer root sheath
K17, K6b	Epidermal appendages
K19	Simple epithelia, epidermal appendages
K20	Gastrointestinal tract
hHb5 (now K85)	Hair, nails
hHb6, hHb1 (now K81, K86)	Cortical trichocytes
K25irs 1–4	Inner root sheath (type I keratins)
K71–74	Inner root sheath (type II keratins)

Readers should refer to the new consensus nomenclature for mammalian keratins published by Schweizer *et al.* in *J Cell Biol* 2006; 174: 169–174.

keratins are coexpressed in specific pairings with one from each type.⁴ For example, in the basal layer the keratins are K5 and K14 and in the suprabasal layers K1 and K10. K15 has no defined type II partner.⁶ Keratins additional to a pair are sometimes found. For example, K6, K16, and K17 are found in the nail bed epithelium. A new keratin, designated K6irs, has been localized to the inner root sheath of the hair follicle.⁷

Keratins exhibit a high degree of tissue specificity. The primary location of each of the keratin types is shown in Table 9.1, which is based on Irvine and McLean's work⁸ and a later paper by Chu and Weiss.⁹ Keratin mutations can cause epithelial fragility syndromes, such as epidermolysis bullosa simplex, in addition to some of the ichthyoses and keratodermas.⁸ The various disorders of keratin and their corresponding keratin mutation are listed in Table 9.2.

The keratin intermediate filaments aggregate into bundles (tonofilaments) that touch the nuclear membrane and extend through the cytoplasm to interconnect with adjacent cells, indirectly, via the desmosomal plaques.^{4,10}

The keratohyaline granules that give the identifying features to the granular layer result from the accumulation of newly synthesized proteins. One of these is *profilaggrin*. It undergoes dephosphorylation to form *filaggrin*, a histidine-rich protein that acts as a matrix glue and facilitates filament aggregation into even larger bundles. Filaggrin rapidly aggregates the keratin cytoskeleton, causing collapse of the granular cells into flattened anuclear squames.¹¹ Trichohyalin, found primarily in the inner root sheath cells, is sometimes coexpressed with filaggrin.¹² The keratin filaments are stabilized by disulfide cross-links that make this intracytoplasmic structural mesh highly insoluble. A second polypeptide, *loricrin*, is localized to the keratohyaline granules. It contributes to the formation of a stable, intracytoplasmic, insoluble barrier known as the *cell envelope* (*cornified envelope*) (see later).

Table 9.2 Disorders of keratin

Disease	Keratin mutation
Bullous congenital ichthyosiform erythroderma	K1, K10
Ichthyosis bullosa of Siemens	K2e
Ichthyosis hystrix of Curth–Macklin	K1
Epidermolytic palmoplantar keratoderma	K9, K1 (some cases)
Non-epidermolytic palmoplantar keratoderma	K1 (one family) type II keratin cluster (not yet clarified)
Palmoplantar keratosis with anogenital leukokeratosis	K6, K16
Focal non-epidermolytic palmoplantar keratoderma	K1, K16
Unna–Thost palmoplantar keratoderma	K1, K16
Unilateral palmoplantar verrucous nevus	K16
Striate palmoplantar keratoderma (type III)	K1
Pachyonychia congenita	K6a, K6b, K16, K17
White sponge nevus	K4, K13
Monilethrix	K81, K86
Epidermolysis bullosa simplex	K5, K14

The granular layer also contains small, lipid-rich lamellated granules (100–500 nm in diameter), known as *Odland bodies* or *membrane-coating granules*. They are secreted into the intercellular space in this region. Their lipid-rich nature contributes to the permeability barrier (see later).¹³

The *cell envelope* (*cornified envelope*) forms just beneath the cell membrane. It is 7–15 nm wide and composed of cross-linked proteins. Several proteins are involved in the formation of the cell envelope, including loricrin, involucrin, keratolinin, and small proline-rich proteins.^{4,14} Polymerization and cross-linking of these proteins requires the action of calcium-dependent epidermal transglutaminases, of which three have been identified in the skin. The heat shock protein hsp27 appears to play a role in the assembly of the cornified cell envelope.¹⁵

Keratinocytes in the stratum corneum (corneocytes) are dead. They eventually undergo desquamation, an orderly process in which individual corneocytes detach from their neighbors at the skin surface and are swept away.¹⁶ This occurs, in part, because the desmosomes are degraded (presumably by proteases) during transit through the stratum corneum.¹⁷ One of these enzymes is stratum corneum chymotryptic enzyme, a serine protease that causes proteolysis of desmosomes in the stratum corneum. It is reduced, but not absent, in the ichthyoses.¹⁸ However, the process of desquamation (dyshesion) is more complex than simple desmosomal degeneration.¹⁹ It is known that cholesterol esters are important components of cell adhesion. For example, in X-linked ichthyosis, there is an accumulation of cholesterol sulfate associated with a deficiency in aryl sulfatase, which results in decreased desquamation and keratin accumulation. It is thought that cholesterol sulfate inhibits proteases that are involved in desquamation.²⁰ Lipids also play a role in the permeability barrier of the skin, a function that resides in the region of the granular layer.^{21,22} Lipids secreted by the Odland bodies (discussed above) are an important component of the permeability barrier. In addition to the structures already described, there is a skin surface lipid film produced by secreted sebum mixed with lipid from the keratinizing epithelium.²³ It contributes to barrier function.

Table 9.3 Disorders of keratinization

Abnormal process	Diseases with this abnormal process
Calcium pump	Darier's disease Hailey–Hailey disease
Sulfatase disorders	X-linked ichthyosis Kallmann's syndrome (ichthyosis and hypogonadism) Multiple sulfatase deficiency X-linked recessive chondrodysplasia punctata
Keratin disorders	See Table 9.2
Desmosomal defects (desmoplakin; cadherins)	Carvajal syndrome (desmoplakin) Striate palmoplantar keratoderma (type I desmoglein; II desmoplakin) Naxos disease (plakoglobin) Ectodermal dysplasia/skin fragility syndrome (plakophilin)
Tight junction (claudin)	ILVASC
Processing of filaggrin	Granular parakeratosis Ichthyosis vulgaris (AGL variant)
Loricrin	Progressive symmetrical erythrokeratoderma (PSEK)–loricrin variant Vohwinkel's syndrome (ichthyotic variant)
Precursor proteins of cell envelope	Camisa keratoderma PSEK (loricrin variant)
Absence of LEKT1	Netherton's syndrome
Connexin	Erythrokeratoderma variabilis Vohwinkel's syndrome (keratoderma variant) KID syndrome Hidrotic ectodermal dysplasia Oculodentodigital dysplasia
Abnormal lipid metabolism	Sjögren–Larsson syndrome (fatty aldehyde dehydrogenase gene) Conradi–Hünermann–Happle syndrome (included as peroxisomal by some) CHILD syndrome (included as peroxisomal by some) Neutral lipid storage disease
Peroxisomes	Refsum's disease (increased phytanic acid) Chondrodysplasia punctata (two variants)
Lamellar granules	Harlequin ichthyosis
Cell envelope (transglutaminase-1) (transglutaminase-5)	Lamellar ichthyosis Congenital ichthyosiform erythroderma (50%) Peeling skin syndrome (acral type)
Proteinase disorders	Papillon–Lefèvre syndrome (cathepsin C gene) Haim–Munk syndrome

The chromosomal localizations of the various genes encoding the various polypeptides involved in keratinization have been elucidated: type I keratins on chromosome 17, type II on chromosome 12, transglutaminases on chromosome 14, and profilaggrin, trichohyalin, loricrin, involucrin, and the small proline-rich proteins on chromosome 1q21.⁴ Because this latter gene complex controls the structural proteins of cornification, the term 'epidermal differentiation complex' has been proposed for this region.¹⁴ The expression of these genes is controlled by proteins called transcription factors.^{24,25}

The abnormal process, where known, for each of the disorders of keratinization is shown in [Table 9.3](#). This is based on a publication by Hohl.²⁶

ICHTHYOSES

The ichthyoses are a heterogeneous group of hereditary and acquired disorders of keratinization characterized by the presence of visible scales on the skin surface.^{27–30} The word is derived from the Greek root for fish – *ichthys*. There are four major types of ichthyosis: ichthyosis vulgaris, X-linked ichthyosis, ichthyosis congenita, and epidermolytic hyperkeratosis (bullous ichthyosiform erythroderma). In addition, there are several rare syndromes in which ichthyosis is a major feature. It has been estimated that nearly 1 million Americans have either ichthyosis vulgaris or X-linked recessive ichthyosis, the most common forms.³¹ For patients, family, and friends requiring information, this can be found on the website of the Foundation for Ichthyosis and Related Skin Types at <http://www.firstskinfoundation.org/>.³²

Kinetic studies have shown that lamellar ichthyosis and epidermolytic hyperkeratosis are characterized by hyperproliferation of the epidermis with transit times of 4 or 5 days, whereas the scale in ichthyosis vulgaris and X-linked ichthyosis is related to prolonged retention of the stratum corneum (retention hyperkeratosis).^{17,27,28} This may be related to a persistence of desmosomes in the stratum corneum.³³

Although the mode of inheritance was originally used as a major criterion in the delineation of the various forms of ichthyosis, recent studies have shown evidence of genetic heterogeneity in the various groups.^{34,35} Consanguinity is an important association in some communities.^{36,37} Our understanding of the molecular basis of many of the ichthyoses has progressed tremendously in approximately the past decade.³⁸

Oral retinoid therapy is often used in the treatment of disorders of keratinization including the ichthyoses. A retrospective study involving patients on this treatment for up to 25 years reported disappointing results, with nearly 50% of patients experiencing no benefit ± side effects.³⁹ Work is ongoing to develop a drug for the ichthyoses with a more favorable tolerability profile than retinoids such as acitretin. One such drug may be liarozole, an imidazole given orphan drug status by the European Commission and the U.S. Food and Drug Administration.⁴⁰ In a phase II/III, double-blind, randomized trial, liarozole is equally effective as a treatment for ichthyosis as acitretin, but it shows a trend toward a more favorable tolerability profile.⁴⁰

ICHTHYOSIS VULGARIS

Ichthyosis vulgaris (OMIM 146700) is the most common disorder of keratinization (incidence 1 : 250), with an onset in early childhood and an autosomal dominant inheritance.^{27,37} Heterozygotes show a very mild phenotype with incomplete penetrance (semidominant); such cases may be misdiagnosed as dry skin.^{11,41} The disorder is lifelong. It is characterized by fine, whitish scales involving particularly the extensor surfaces of the arms and legs, as well as the scalp. Flexures are spared. There may be accentuation of palmar and plantar markings, keratosis pilaris, and features of atopy.

In ichthyosis vulgaris, there is a deficiency in profilaggrin, which is converted into filaggrin, the major protein of keratohyalin.^{17,42} There are quantitative decreases in filaggrin, related to the severity of the disease.⁴³ This results from loss-of-function mutations in the gene encoding filaggrin (*FLG*), located at 10q21.^{11,44–46} The gene is unusually large and repetitive, making analysis of it difficult.¹¹ Mutations in the *FLG* gene occur in approximately 9% of individuals from European populations.⁴⁷ Childhood eczema is strongly associated with these common European mutations.^{48,49} A previously unreported genetic locus for ichthyosis vulgaris has been identified in two Chinese families on chromosome 10q22.3–q24.2.⁵⁰ No specific gene has, as yet, been identified. In fact, a variety of mutations of this gene have

been identified, and there appear to be ethnic differences among *FLG* mutations found in Asians and Europeans, with some variances also among these populations.^{51–53} Although filaggrin is an intracellular protein, deficiencies result in alterations of keratinocyte architecture that influence extracellular matrix functions. These architectural changes include altered keratin filament organization, impaired loading of lamellar body contents, irregular extracellular distribution of secreted organelle material, and changes in lamellar bilayer architecture.⁵⁴ One study showed that a complete filaggrin deficiency in ichthyosis vulgaris resulted in only moderate changes in epidermal permeability barrier function.⁵⁵ It has also been shown that patients with ichthyosis vulgaris associated with atopic dermatitis had a lower percentage of filaggrin mutations than was the case among those with isolated ichthyosis vulgaris but still had markedly reduced intraepidermal expression of profilaggrin/filaggrin peptides, suggesting that there may be other factors that downregulate profilaggrin/filaggrin expression in these patients.⁵⁶ A global clinical severity score of 4 or less – based on skin xerosis, hyperlinearity of the palms, scale on the legs, scalp desquamation, and keratosis pilaris – has been found to have a good negative predictive value of the common Caucasian null *FLG* mutations R501X and 2282del4 and may therefore be helpful in screening for these mutations.⁵⁷

Treatment of ichthyosis vulgaris depends on the severity of the disease; it includes emollients and keratolytics, including, respectively, 12% ammonium lactate cream or lotion and 6% salicylic acid gel. Other agents contain urea or propylene glycols.⁵⁸ Topical retinoids may also be beneficial. Compounds that increase filaggrin expression in keratinocytes, such as oleanolic acid and ursolic acid, and other products in medicinal herbs and plants, may prove to be useful.⁴⁷

Histopathology

The epidermis may be of normal thickness or slightly thinned with some loss of the rete ridges.⁵⁹ There is mild to moderate hyperkeratosis, associated paradoxically with diminution or absence of the granular layer (Fig. 9.1). The thickened stratum corneum is often laminated in appearance. The hyperkeratosis may extend into the hair follicles. The sebaceous and sweat glands are often reduced in size and number.

Electron microscopy

Electron microscopy shows defective keratohyaline synthesis with small granules having a crumbled or spongy appearance.⁴²

Figure 9.1 Ichthyosis vulgaris. There is a thickened layer of compact orthokeratosis overlying a diminished granular layer. (H&E)

Differential diagnosis

Because the microscopic changes are sometimes quite mild, biopsies may be interpreted as 'normal skin', particularly in the absence of a clinical history. Therefore, ichthyosis vulgaris is often included in the differential diagnosis of 'nothing lesions'. The keys to diagnosis include compact orthokeratosis and a markedly diminished to absent granular cell layer. The microscopic findings in acquired ichthyosis and pityriasis rotunda are frequently identical to those in inherited ichthyosis vulgaris (discussed later). In such cases, clinical history (onset later in life, association with neoplasia, nutritional deficiency, or drugs) is essential in pointing to a diagnosis other than ichthyosis vulgaris.

X-LINKED ICHTHYOSIS

This form of ichthyosis (OMIM 308100), which is inherited as an X-linked recessive trait, is present at birth or develops in the first few months of life. It is characterized by large polygonal scales that are dirty brown in color and adherent. X-linked ichthyosis may involve the entire body in varying degree, although there is sparing of the palms and soles. The preauricular region is characteristically involved in this variant of ichthyosis; in contrast, this site is usually spared in ichthyosis vulgaris.⁶⁰ Corneal opacities and mental retardation may also occur in X-linked ichthyosis.^{61–64} Other rare associations include congenital dislocation of the hip,⁶⁵ Poland's syndrome (unilateral absence of the pectoralis major muscle; OMIM 173800),⁶⁶ and Kallmann's syndrome (hypogonadism, renal agenesis, anosmia, and synkinesis; OMIM 308700).⁶⁷ Interestingly, X-linked ichthyosis and Kallmann's syndrome result from abnormalities in contiguous genes.⁶⁷ It has also been associated with the oculo-auriculo-vertebral spectrum (Goldenhar syndrome; OMIM 164210).⁶⁸ An association with steroid-resistant nephrotic syndrome has been reported.⁶⁹ Ichthyosis vulgaris and X-linked ichthyosis have been reported in the same family (see later).⁷⁰ Male-pattern baldness does occur, despite earlier claims to the contrary.^{71,72} Coexistence of X-linked ichthyosis with dominant⁷³ and recessive⁷⁴ dystrophic epidermolysis bullosa has been reported. The patient with recessive dystrophic epidermolysis bullosa had a partial deletion of the steroid sulfatase gene and a recessive point mutation in the *COL7A1* gene.⁷⁴

Its incidence is approximately 1 in 5000–6000 males, but occasionally female heterozygotes have mild scaling of the legs.⁶⁴ Full expression of the disease has only been reported in a few females.⁷⁵ In a recent case of a female with severe ichthyosis and atopic eczema, both a steroid sulfatase deletion mutation and a frameshift mutation in the gene encoding filaggrin (a finding of ichthyosis vulgaris) were found.⁷⁶

This condition is characterized by a deficiency of steroid sulfatase in a wide range of tissues, including leukocytes and fibroblasts. As a result, there is an accumulation of cholesterol sulfate in the pathological scales and in serum and leukocytes.^{16,77–80} Accumulation in the skin interferes with normal barrier function^{81,82} and with proteases involved in the dissolution of desmosomes required for desquamation of the stratum corneum.²⁰ There are elevated levels of cholesterol sulfate and dehydroepiandrosterone in the serum.⁸³ The deficiency in placental sulfatase that is also present results in decreased maternal urinary estrogens and a failure to initiate labor in some cases.⁶¹ The steroid sulfatase (*STS*) gene is on the distal short arm of the X chromosome (Xp22.3).⁶² Most cases involve complete or partial deletion of the *STS* gene and flanking sequences.^{84–91} The defect is usually inherited, and it is not due to a *de novo* mutation.⁹² In most cases, there appears to be paternal transmission of the affected X chromosome.⁹¹ Fluorescence *in situ* hybridization analysis is best performed for an accurate diagnosis of the female carrier state.⁹³

Treatment regimens similar to those for ichthyosis vulgaris can be used.

Figure 9.2 X-linked ichthyosis. Findings include a thickened stratum corneum, the presence of a granular cell layer, and acanthosis. Hyperkeratosis of a sweat duct orifice is noted. (H&E)

Histopathology

There is usually conspicuous acanthosis with thickening of the stratum corneum and a normal to thickened granular layer. Acanthosis was absent in all nine cases studied in one series.⁹⁴ Thinning of the granular layer is sometimes present.⁹⁵ There is often hyperkeratosis of follicular and sweat duct orifices (Fig. 9.2).⁹⁶ Suprabasal and basal vacuolation are sometimes present.⁹⁴ There may be a few lymphocytes around the vessels in the superficial dermis.

Differential diagnosis

The presence of compact orthokeratosis, in the absence of other significant histopathologic abnormalities, should suggest the possibility of ichthyosis of a variety of types, including X-linked ichthyosis. Suspicions for this disorder would increase if the patient is a young boy. However, the microscopic findings could be similar in acquired ichthyosis or syndromal ichthyosis. A normal to slightly thickened granular cell layer would argue against ichthyosis vulgaris, but forms of X-linked ichthyosis with a reduced granular cell layer may be difficult to distinguish from ichthyosis vulgaris without other clinical or laboratory data (e.g., an atopic diathesis, which favors ichthyosis vulgaris, and steroid sulfatase deficiency, which indicates a diagnosis of X-linked ichthyosis). There is also literature on an X-linked *dominant* ichthyosis, but this is in reality a rare subgroup of the Conradi–Hünemann–Happle syndrome (see later). It is caused by mutations in the 3 β -hydroxysteroid- Δ 8, Δ 7-isomerase (emopamil-binding protein; EBP) gene, which is found on the short arm of the X chromosome at Xp11.22–p11.23. The ichthyosis presents at birth as a collodion membrane, and it evolves into a generalized or erythrodermic picture, eventually forming whorls of scale. These patients also may have striate palmar lesions, scarring alopecia, limb shortening, congenital dislocation of the hip, cataracts, and abnormal facies. Skin biopsy findings resemble those of ichthyosis vulgaris, with a diminished granular cell layer and later-stage perifollicular atrophy.⁹⁷

ICHTHYOSIS CONGENITA

In recent years, there has been an attempt to reclassify the autosomal recessive ichthyoses previously known as lamellar ichthyosis (LI) and

nonbullous congenital ichthyosiform erythroderma (CIE) as ichthyosis congenita on the basis of ultrastructural findings suggesting that there are at least four types.^{98–100} It has an estimated prevalence of 1 in 300,000 newborns, and most of the infants are born as ‘collodion babies’.¹⁰¹ This new classification has not yet been widely accepted by clinicians; furthermore, inheritance and ultrastructure have not always proven to be a reliable basis for classifications. A defect in keratinocyte transglutaminase has been detected in approximately 50% of the families studied.¹⁰²

To date, six genes have been identified for autosomal recessive congenital ichthyosis: *TGM1* on chromosome 14q11, *ABCA12* on chromosome 2q34–q35,¹⁰³ *ichthyin* on chromosome 5q33, *ALOXE3* and *ALOX12B* on chromosome 7p13, and *CYP4F22* (*FLJ39501*) on chromosome 19p12–q12.^{101,104–106} Two additional loci have been identified, the first on chromosome 19p13.2–p13.1 (? *CYP4F22*) and the second on chromosome 12p11.2–q13.¹⁰¹ In addition, mutations in *CG1-58/ABHD5* on chromosome 3p21 have been found to underlie Chanarin–Dorfman syndrome (OMIM 275630).¹⁰¹ Another syndromic congenital ichthyosis is hypotrichosis, caused by a mutation in *ST14* on 11q24.3–q25. The gene encodes the serum protease matriptase.¹⁰⁷ The genes in the LOX cluster are involved in the subset of congenital ichthyosis known as (nonbullous) congenital ichthyosiform erythroderma.¹⁰¹

The four subtypes of ichthyosis congenita are discussed next. This classification may need to be modified or abandoned because overlapping ultrastructural features have been reported between some of the types.¹⁰⁸

Type I

Type I is the largest group and corresponds to CIE of the older classification (see later). There is erythroderma with fine scaling. Approximately 40% present as a ‘collodion baby’, in which the infant is encased in a tight membrane.¹⁰⁰ Most have palmoplantar keratoderma. Clear ultrastructural criteria are lacking, but numerous lipid droplets are usually present in the horny cells.⁹⁹ It has been suggested that the diagnosis be made by exclusion of the other three types. This group may still be heterogeneous.

Type II

Type II is characterized by cholesterol clefts in the horny cells. It corresponds to lamellar ichthyosis (see later).

Type III

There is generalized lamellar scaling with a pronounced reticulate pattern. There is erythroderma and pruritus. This group usually presents as a collodion baby. There are perinuclear, elongated membrane structures in the granular and horny cells.^{99,109}

Type IV

There is a variable clinical phenotype. Types III and IV were both previously included with CIE.¹¹⁰ There are masses of lipid membranes in the granular and horny cells. A case that clinically resembled diffuse cutaneous mastocytosis has been reported.¹¹¹

Lamellar ichthyosis

Lamellar ichthyosis (OMIM 242300) is characterized by large plate-like scales of ichthyosis.¹¹² It corresponds to ichthyosis congenita type II (discussed previously). It may present as a ‘collodion baby’.^{28,113–116} The palms and soles are often involved.²⁸ Nail plates are also affected.¹¹⁷ Pseudoainhum has also been reported.¹¹⁸ It accounted for 5.6% of all ichthyoses in one series from Saudi Arabia.³⁶ An increased incidence of skin cancers has been reported in this variant of ichthyosis.¹¹⁹ It has also been associated with rickets,¹²⁰ 25-hydroxyvitamin D deficiency,¹²¹ celiac disease,¹²² and dermatophytosis.¹²³

This variant has been shown to have mutations in the keratinocyte transglutaminase-1 (*TGM1*) gene on chromosome 14q11.1.^{124–132} Plasminogen activator inhibitor-2, a substrate of transglutaminase-1, has normal expression in a large group of TGase-1-proficient congenital ichthyosis, making it unlikely that this inhibitor is a primary molecular cause of this type of ichthyosis.¹³³ This defect in transglutaminase-1 interferes with the cross-linkage of loricrin and involucrin and the formation of the cornified cell envelope.¹³⁴

A highly preferred substrate peptide for transglutaminase-1, K5 (pepK5), has been found to be a very effective screening tool for the molecular diagnosis of transglutaminase-1-deficient lamellar ichthyosis.¹³⁵ A second variant of lamellar ichthyosis (OMIM 601277) is due to mutations in the *ABCA12* gene (an ATP binding cassette-4 protein), which has been mapped to chromosome 2q34–q35.

Collodion babies should be treated in a humidified incubator, if necessary with intravenous hydration.¹¹⁶ The use of emollients seems to predispose to skin infections.¹¹⁶ Most collodion babies progress into a form of autosomal recessive ichthyosis congenita.¹¹⁶

Congenital ichthyosiform erythroderma

CIE was known in the past as nonbullous congenital ichthyosiform erythroderma (OMIM 242100). It has also been included within the category of lamellar ichthyosis. CIE is known to be a heterogeneous entity;¹³⁶ variants have been reclassified as ichthyosis congenita types I, III, and IV (discussed previously). Consanguinity is high.¹³⁷ Variants include a pustular form¹³⁸ and a reticulated pigmented form (ichthyosis variegata).^{139,140} Most present as collodion babies.¹³⁷ Note that loricrin keratoderma (see p. 289) can also present as a collodion baby and mimic CIE.¹⁴¹ A patient with associated ocular albinism and Noonan’s syndrome has been reported.¹⁴² Multiple aggressive squamous cell carcinomas developed in one patient with CIE.¹⁴³ CIE differs from LI by the erythroderma and finer, pale scales that have a high content of *n*-alkanes.^{78,144,145} A subset of patients with CIE may have abnormal expression of keratinocyte transglutaminase-1,¹⁴⁶ but the genes most commonly implicated in this variant are part of the LOX gene cluster – *ALOXE3* and *ALOX12B* on chromosome 17p13^{101,147–149} and *ABCA12* on 2q34–q35.¹⁰³ One patient with a novel *ALOX12B* mutation p.Arg442Gin as well as an established p.Arg432X mutation was found to have abnormal secretion of lamellar granule contents within the epidermis.¹⁵⁰

Oral retinoids have been used to treat this condition.¹⁵¹

Histopathology

Some of the reports in the literature have not distinguished between LI and CIE or the various subtypes of ichthyosis congenita; a composite description therefore follows. However, in the study from the Great Ormond Street Hospital in London, nonbullous ichthyosiform erythroderma and LI were histologically indistinguishable.⁹⁴

There is hyperkeratosis, focal parakeratosis, and a normal or thickened granular layer.¹⁵² The hyperkeratosis is more marked in LI than other variants, and there is easily discernible parakeratosis in CIE.¹⁴⁴ There is often some acanthosis, and occasionally there is irregular psoriasiform epidermal hyperplasia (Figs. 9.3 and 9.4).³⁵ Vacuolation of cells in the granular layer is a rare finding.¹⁵³ Keratotic plugging of follicular orifices may also be present. The dermis often shows a mild superficial perivascular infiltrate of lymphocytes.

The case presented recently with ichthyosiform erythroderma, onset in adolescence, and a lichenoid tissue reaction on histology probably represents a new entity.¹⁵⁴

Electron microscopy

The ultrastructural features of the various types of ichthyosis congenita (including LI and CIE) have been outlined previously.

Figure 9.3 Lamellar ichthyosis. There is compact orthokeratosis and mild psoriasiform hyperplasia of the epidermis. (H&E)

Figure 9.4 Lamellar ichthyosis. Another case with more orthokeratosis and a less regular outline. (H&E)

Differential diagnosis

A review of past microscopic descriptions would suggest considerable overlap of the findings of LI and CIE, but based on the findings of Williams and Elias¹⁵⁵ and our own experience, the features can be quite different once past the collodion membrane stage. LI tends to show compact orthokeratosis, without parakeratosis, and acanthosis that is not pronounced, whereas CIE is apt to show parakeratosis and psoriasiform acanthosis. LI could be confused with examples of X-linked, acquired, or syndromal ichthyosis, but the compact orthokeratosis and prominent granular cell layer argue against ichthyosis vulgaris. CIE could potentially be confused with psoriasis, spongiotic dermatitis with psoriasiform acanthosis, or erythroderma due to other causes. The prominent granular cell layer and the absence of neutrophils allows distinction from psoriasis, and spongiotic changes would not be expected in lesions that have not been secondarily eczematized.

BULLOUS ICHTHYOSIS

The term ‘bullous ichthyosis’ is preferred to bullous congenital ichthyosiform erythroderma (OMIM 113800) and to epidermolytic hyper-

keratosis (which merely describes a histological reaction pattern).^{156–158} Despite this confusion in terminology, there is a resurgence in the use of the term epidermolytic hyperkeratosis.^{159,160} Bullous ichthyosis is a rare, autosomal dominant condition that is usually severe and characterized at birth by widespread erythema and some blistering.²⁸ Coarse, verrucous scales, particularly in the flexures, develop as the disposition to blistering subsides during childhood. Annular plaques, of late onset, have been reported.¹⁶¹ It has been associated with hypocalcemic vitamin D-resistant rickets.¹⁶² Multiple non-melanoma skin cancers, some particularly aggressive, have been reported in a limited number of cases.¹⁶³

Bullous ichthyosis is a clinically heterogeneous condition.^{164–169} Six subtypes have been defined, with the presence or absence of palmoplantar keratoderma being used as a major feature in defining them.¹⁷⁰ There is evidence that cases with severe palmoplantar keratoderma (type PS-1) have abnormalities in *KRT1*, whereas those without have abnormalities in *KRT10*.^{160,171–173} Among cases with point mutations at the helix initiation motif and the helix termination motif of *KRT1*, a high proportion presenting as generalized epidermolytic hyperkeratosis with severe palmoplantar keratoderma showed missense mutations in the heptad repeat position a, d, e, and g. This result suggests that the mutation site and its consequent protein alterations may correlate with the phenotype of severe palmoplantar keratoderma.¹⁷⁴ In cases of palmoplantar keratoderma without diffuse cutaneous lesions, defects in *KRT9* are usual. The most common abnormality in *KRT10* involves an arginine-to-histidine substitution at one point.^{175,176} Other substitutions have been reported.^{177–179} No abnormality in *KRT1* or *KRT10* has been detected in some cases, suggesting that other genes may be involved. Keratins 1 and 10 are coexpressed to form keratin intermediate filaments in the suprabasal layers of the epidermis.^{168,170,180–183} The *KRT1* and *KRT10* genes are located on chromosome 12 in the type II keratin cluster. Approximately 50% of cases involve spontaneous mutations in either gene.¹⁸⁴ Clinical variants of bullous ichthyosis include a rare *acral group* (not included in the six subtypes mentioned previously),¹⁰ an *annular form* (due in one case to a *KRT10* mutation),^{181,185,186} *ichthyosis hystrix of Curth–Macklin* (OMIM 146590) due to mutations in the keratin 1 (*KRT1*) gene at 12q13 and characterized ultrastructurally by perinuclear shells of unbroken tonofilaments,¹⁸⁷ *ichthyosis hystrix of Lambert*,^{188,189} and *ichthyosis bullosa of Siemens*.^{190–199} Ichthyosis bullosa of Siemens (OMIM 146800) is due to mutations in the keratin 2e gene (*KRT2*) at 12q11–q13, in contrast to the mutations in keratin 1 or 10 in patients with epidermolytic hyperkeratosis/bullous congenital ichthyosiform erythroderma.^{200,201} It is autosomal dominant. The hyperkeratosis is usually limited to the flexural areas, and there is no erythroderma.²⁰² There is circumscribed shedding of the stratum corneum over hyperkeratotic skin (the Mauserung phenomenon).^{202–204} *Ichthyosis exfoliativa* (exfoliative ichthyosis; OMIM 607936) is said to have a similar genetic defect and clinical features to ichthyosis bullosa of Siemens, but one report suggested that there is no epidermolytic hyperkeratosis on histology.^{205,206} It also appears to be autosomal recessive with linkage to 12q13.^{207,208}

Prenatal diagnosis can be made at approximately 19 weeks by fetal skin biopsy examined by light and electron microscopy.²⁰⁹ It can be made earlier (10 or 11 weeks of gestation) by direct gene sequencing of chorionic villus samples.^{210,211}

Retinoid therapy is particularly effective in patients with *KRT10* mutations but not in patients with *KRT1* mutations.²¹² The mosaic form of this disease has been successfully treated with topical maxacalcitol, a vitamin D₃ analogue with approximately 10 times greater efficacy at suppressing keratinocyte proliferation *in vitro* than calcipotriol.²¹³

Histopathology

The histological pattern is that of epidermolytic hyperkeratosis, characterized by marked hyperkeratosis and granular and vacuolar change

Figure 9.5 Bullous ichthyosis with hyperkeratosis and granular and vacuolar change of the keratinocytes in the upper layers of the epidermis. Blistering is not shown in this field. (H&E)

in the upper spinous and granular layers (Fig. 9.5).²¹⁴ Intracytoplasmic and perinuclear eosinophilic homogenizations are identified with varying frequencies. They correspond to the aggregation of tonofilaments seen on electron microscopy.²¹⁵ The keratohyaline granules appear coarse and basophilic with clumping. There is moderate acanthosis. The histological features of blistering can sometimes be subtle, with only slight separation of the markedly vacuolar cells in the mid and upper epidermis. There is usually a mild perivascular inflammatory cell infiltrate in the upper dermis.

In *ichthyosis bullosa of Siemens*, the changes are usually confined to the granular layer and the superficial spinous cells.²⁰²

Electron microscopy

There is aggregation of tonofilaments at the cell periphery with perinuclear areas free of tonofilaments and containing endoplasmic reticulum.^{216,217} In the upper granular layer, there are numerous keratohyaline granules, sometimes embedded in clumped tonofilaments. Although desmosomes appear normal, there is often an abnormality in the association of tonofilaments and desmosomes.

Differential diagnosis

The changes of epidermolytic hyperkeratosis are unique among the other forms of ichthyosis. However, the same microscopic features can be seen in palmoplantar keratoderma (Vörner type) without ichthyosis, a variant of linear epidermal nevus (ichthyosis hyxtrix), solitary and disseminated epidermolytic acanthoma, and as an incidental finding in biopsy or re-excision specimens. An example of Grover's disease with microscopic findings of epidermolytic hyperkeratosis has been described.²¹⁸ Early or mild lesions of epidermolytic hyperkeratosis with changes concentrated in the region of the granular cell layer can mimic verruca plana, but the latter should display basket-woven stratum corneum and round, basophilic nuclei at the centers of the vacuolated cells, without associated irregular keratohyalin granules or clumped keratin filaments.

NETHERTON'S SYNDROME

Netherton's syndrome (OMIM 256500) is a rare autosomal recessive disease characterized by the triad of ichthyosis, trichorrhexis invaginata (bamboo hair), and an atopic diathesis with elevated levels of IgE.^{219–227} Infants are usually born with ichthyosiform

erythroderma, which may persist²²⁸ or eventually become a milder, migratory, and polycyclic ichthyosis known as ichthyosis linearis circumflexa (ILC). Patches of ILC do not usually appear until after the first year of life, sometimes delaying the diagnosis.^{229–232} Other clinical manifestations include intermittent aminoaciduria, elevated serum levels of interleukin-18 (IL-18), mental retardation, enteropathy, and hemihypertrophy.^{233,234}

Netherton's syndrome is due to mutations of *SPINK5* on chromosome 5q32.^{235,236} It is telomeric to the cytokine gene cluster at 5q31.²³⁷ *SPINK5* encodes the lymphoepithelial Kazal-type-related inhibitor (LEKTI), a serine protease inhibitor that has a crucial role in epidermal growth and differentiation.^{230,235,236,238,239} An immunohistochemical test for the presence of LEKTI in skin has been developed. LEKTI is absent in Netherton's syndrome.²⁴⁰ There is some correlation between the mutations and the phenotype.²⁴¹ Preimplantation genetic diagnosis of Netherton's syndrome has been successfully carried out.²⁴² There is evidence that overexpression of elastase 2 (localized to keratohyaline granules) may result in abnormal pro-filaggrin processing, thus resulting in abnormal lipid lamellae structure and, therefore, impaired skin barrier function in these patients.²⁴³

Other hair shaft abnormalities, such as pili torti, trichorrhexis nodosa, and monilethrix, have also been reported in Netherton's syndrome.^{244,245} The hair shaft abnormalities are more common in eyebrow than scalp hair.²⁴⁶ Hair shaft changes may not appear until 18 months of age.²⁴⁷ The diagnosis has been made by dermoscopy of the hairs in one suspected case; trichorrhexis invaginata was present.²⁴⁸

Disturbances in the immune system have been reported in several patients with Netherton's syndrome.²⁴⁹ This may be the explanation for the finding of infections, including HPV infection, superimposed on the ichthyotic lesions.^{250,251} Squamous cell carcinomas may develop,²⁵² as have multiple non-melanoma skin cancers.²⁵³ CD30⁺ T-cell lymphoma developed in one patient with Netherton's syndrome who underwent a heart transplant for idiopathic cardiomyopathy.²³⁸ Cases with phenotypic overlap with the peeling skin syndrome (see p. 318) have been reported.^{254–256} The keratin filaments from the scales in Netherton's syndrome are composed of reduced amounts of high-molecular subunits and increased amounts of low-molecular subunits.²¹⁹ Some patients may have ILC in the absence of features of Netherton's syndrome.

Various treatments have been used with variable success. These include emollients as adjunctive therapy, short-term use of topical corticosteroids, topical retinoids (although they can aggravate the condition over the long term), topical calcipotriol, PUVA, cyclosporine (ciclosporin), ammonium lactate 12% lotion,²⁵⁷ pimecrolimus,^{257,258} tacrolimus (with variable success),^{227,257} infliximab infusion,²⁵⁹ and narrowband UVB therapy.^{260,261}

Histopathology

The skin lesions show hyperkeratosis, a well-developed granular layer, and acanthosis. The margin shows focal parakeratosis with absence of the granular layer and more obvious psoriasiform epidermal hyperplasia (Fig. 9.6).^{219,262,263} In erythrodermic cases, the parakeratosis is more prominent; sometimes, it constitutes the entire stratum corneum. In all cases, the outermost nucleated layers do not flatten normally.²²⁸ Pustules are sometimes seen in the erythrodermic stage. Epidermal mitoses are increased. In some cases, PAS-positive, diastase-resistant granules can be found in the prickle cells. There is often a mild perivascular inflammatory cell infiltrate in the superficial dermis.

Differential diagnosis

In the absence of a clinical history or characteristic hair shaft abnormalities, the microscopic features of ILC can resemble those of other forms of ichthyosis, including X-linked ichthyosis, acquired ichthyosis, or even (if a biopsy is obtained from the margins of a polycyclic patch)

Figure 9.6 Ichthyosis linearis circumflexa. This biopsy from a neonate shows a striking resemblance to psoriasis, but there are no mounds of parakeratosis containing neutrophils. (H&E)

CIE. The parakeratosis and acanthosis in this zone could also be confused with psoriasis.

Electron microscopy

Electron microscopy shows an increase in mitochondria and numerous round or oval opaque (lipoid) bodies in the stratum corneum.²¹⁹ A distinctive feature is premature degradation of corneodesmosomes resulting in the secretion of lamellar body contents.^{226,228}

ERYTHROKERATODERMIA VARIABILIS

Erythrokeratoderma variabilis (EKV; OMIM 133200) is a rare, usually autosomal dominant form of ichthyosis that develops in infancy; uncommonly it is present at birth.²⁶⁴ A rare autosomal recessive variant is now recognized.²⁶⁵ There are transient erythematous patches and erythematous hyperkeratotic plaques that are often polycyclic or circinate.^{27,32,266,267} Lesions may resemble erythema gyratum repens.²⁶⁸ A targetoid appearance is seen in the rare cocarde variant.^{269,270} Follicular hyperkeratosis has been described.²⁷¹ There is retention hyperkeratosis associated with a basal cell type of keratin.²⁷²

Figure 9.7 Erythrokeratoderma variabilis. There are hyperkeratosis (basket-woven in this example), papillomatosis, irregular acanthosis, and a mild perivascular lymphocytic infiltrate. Dyskeratotic cells are not evident. (H&E)

The disorder has been mapped to chromosome 1p35.1, but it is genetically heterogeneous. EKV may be caused by mutations in one of two neighboring connexin genes, *GJB3* and *GJB4*, encoding the gap junction proteins Cx31 and Cx30.3, respectively.^{272–277} Sporadic cases also occur. Cases with no identifiable gene defect have been reported.²⁷⁸ Cx31 is expressed predominantly in the stratum granulosum in normal skin.²⁷⁹ The ‘new’ type of erythrokeratoderma reported by van Steensel *et al.*²⁸⁰ has subsequently been reclassified as KLICK syndrome (keratosis linearis with ichthyosis congenita and sclerosing keratoderma; OMIM 601952).^{281,282}

Progressive symmetric erythrokeratoderma (OMIM 602036), thought at one time to be the same condition, appears to be a variant with its own specific abnormality, a mutant loricrin gene.^{26,283} Loricrin and connexin gene mutations were absent in one case.²⁸⁴ It differs from EKV by a greater incidence of palmoplantar keratoderma and the absence of migratory erythematous lesions.²⁸⁵ As the name suggests, the symmetry of the lesions in this variant is more striking.²⁸⁵ Profilaggrin N-terminal domains are aggregated with mutant loricrin within condensed nuclei. These nuclei persist in the cornified layer as parakeratosis.²⁸⁶ The ichthyotic variant of Vohwinkel’s syndrome also has this abnormality. Progressive symmetric erythrokeratoderma could well be reclassified in the future as Vohwinkel’s syndrome or under the simplistic title of loricrin keratoderma (OMIM 604117).²⁸⁷ Heterogeneous phenotypes of loricrin keratoderma may be the result of genetic heterogeneity of loricrin mutations.²⁸⁸

EKV is said to be one of the most responsive genodermatoses to oral retinoids, although their use in children remains controversial.²⁸⁹ Relapse usually occurs on cessation of the treatment.²⁸⁵ Topical tretinoin 0.05% cream has also been used. Others have reported a lack of response to retinoids but success with tazarotene gel.²⁹⁰ Topical tacalcitol has also been used.²⁷⁸ As for all keratotic diseases, emollients and keratolytics should be used first or as adjuvants.

Histopathology

The findings are not distinctive. There is hyperkeratosis, irregular acanthosis, very mild papillomatosis in some biopsies, and a mild superficial perivascular infiltrate of lymphocytes (Fig. 9.7). Dyskeratotic, grain-like cells may be seen in the lower stratum corneum.²⁹¹ There may be parakeratosis and some vacuolation in the lower horny cells and in the granular layer.^{271,292} One report of a case of progressive symmetric erythrokeratoderma described a moderately thickened stratum corneum with focally lamellated parakeratosis, an intact

granular cell layer, acanthosis with mild focal spongiosis, and a sparse superficial perivascular lymphocytic infiltrate in the dermis.²⁹³

Electron microscopy

There is a reduction in keratinosomes in the stratum granulosum.²⁹¹ The dyskeratotic cells have clumped tonofilaments.²⁹¹

HARLEQUIN ICHTHYOSIS

Harlequin ichthyosis (OMIM 242500) is a severe disorder of cornification of autosomal recessive inheritance.^{28,294} There appears to be genetic heterogeneity.²⁹⁵⁻²⁹⁷ It is characterized by thick, plate-like scales over the entire body with deep fissures.²⁹⁸ Ectropion, eclabium, and flat-tended ears are other features of the disease.²⁹⁹ It has been reported in association with hypothyroidism and juvenile rheumatoid arthritis in one patient.³⁰⁰

Although historically considered incompatible with extrauterine life, survivals are becoming more common. In a recent review of 45 cases, there was an overall survival rate of 56%, with the ages of survivors ranging from 10 months to 25 years.³⁰¹ The gene responsible has been identified as *ABCA12*, a member of the adenosine triphosphate-binding cassette (ABC) superfamily of active transporters.^{302,303} The gene maps to chromosome 2q34.³⁰⁴ The *ABCA12* protein is involved in the transportation of key lipids to the stratum corneum and the formation of lamellar granules.^{302,305} Adverse outcomes may be related, in part, to specific mutations; thus, recent work has provided evidence that some missense *ABCA12* mutations in highly conserved transmembrane regions can cause profound changes in protein structure and function, leading to severe clinical phenotypes.^{306,307} Now that DNA diagnosis is available, it allows for robust prenatal and preimplantation testing without the need for fetal skin biopsies.^{302,308} Prenatal skin biopsy was previously carried out at approximately 19 weeks.^{309,310} In countries in which DNA testing is not readily available, a fetal skin biopsy is best done at approximately 23 weeks because of pitfalls in making the diagnosis at an early stage. In some countries, terminations of the pregnancy are only allowed until 20 or 21 weeks of gestation.²⁹⁹

Harlequin ichthyosis is a disorder of epidermal keratinization in which there are altered lamellar granules and a variation in the expression of keratin and filaggrin.^{296,311} Lipid levels may be increased in the stratum corneum.³¹² In some cases, a defect of protein phosphatase has been demonstrated.²⁹⁷ This enzyme may alter the processing of profilaggrin to filaggrin.²⁹⁷

Patients who survive the neonatal period develop a severe exfoliative erythroderma consistent with nonbullous CIE.³¹³ Survival beyond the neonatal period has been enhanced by the use of oral retinoids.³⁰⁴

Histopathology

There is massive hyperkeratosis in all biopsies. Some cases have parakeratosis with a thin or absent granular layer,³¹⁴ whereas others have had persistence of the granular layer.³¹²

Keratinization occurs much earlier in hair canals than in the interfollicular epidermis in fetal skin development.²⁹⁹ Follicular changes occur at approximately 15 weeks of gestation. Interfollicular changes can usually be seen at 19 weeks.²⁹⁹ Terminal hair development is also more developed in the scalp than in vellus hair regions so that the scalp is the best site to biopsy.²⁹⁹ This information is of no relevance where DNA testing is available.

Electron microscopy³¹⁵

The stratum corneum is thickened and contains lipid and vacuolar inclusions.³¹⁶ Lamellar granules are abnormal or absent,^{296,317,318} instead, dense core granules are produced.³¹⁵ The marginal band (cellular

envelope of cornified cells) is present at birth, in contrast to collodion baby in which it is absent at birth but may develop later.^{319,320}

Differential diagnosis

In harlequin ichthyosis, the striking degree of hyperkeratosis, resulting in a stratum corneum thickness 20–30 times that of the underlying epidermis, is distinct from other keratinizing disorders. Cutaneous horns may be markedly hyperkeratotic but are typically seen in older individuals, are limited in radial extent, and are associated with an identifiable underlying lesion, such as a seborrheic keratosis or hypertrophic actinic keratosis. Trichilemmal horns overlie an epidermal depression and demonstrate an absent granular cell layer.

FOLLICULAR ICHTHYOSIS

Follicular ichthyosis (ichthyosis follicularis; OMIM 308205) is a rare, distinctive form of ichthyosis in which the abnormal epidermal differentiation occurs mainly in hair follicles.^{321,322} Clinically, there are spiny follicular papules.³²³ Its onset is at birth or in early childhood. It is an X-linked recessive condition, but two female patients have been reported.³²⁴ The involved gene has not been characterized. The hyperkeratosis is more prominent on the head and neck. Photophobia and alopecia are often present,³²⁵ leading to the acronym IFAP (ichthyosis follicularis, alopecia, atrichia, photophobia).³²³ Three of the patients reported have also had acanthosis nigricans-like lesions.³²¹ The case reported as ‘*ichthyosis cribriformis*’ had keratotic cones and not spiny keratin excrescences,³²⁶ but it may be a related condition.

A moderate response to retinoid therapy has been recorded.³²⁷

Histopathology

There is marked follicular hyperkeratosis that is compact and extends deep within the follicle. There is a prominent granular layer.³²¹ In keratosis pilaris, the hyperkeratosis has a more open basket-weave pattern and is confined to the infundibular region of the follicle.

ACQUIRED ICHTHYOSIS

Acquired ichthyosis, which occurs in adult life, is similar to ichthyosis vulgaris both clinically and histologically.³²⁸ The subject was reviewed in 2006.³²⁹ It is usually associated with an underlying malignant disease, particularly a lymphoma,^{330,331} but it usually appears some time after other manifestations of the malignant process. Acquired ichthyosis and Addisonian pigmentation have been reported in association with multiple myeloma.³³² Ichthyosis has also been associated with malnutrition, sympathectomy,³³³ hypothyroidism,³³⁴ autoimmune thyroiditis,³³⁵ lupus erythematosus,³³⁶ leprosy, HIV infection,³³⁷ HTLV-1 infection,³³⁸ sarcoidosis,^{339,340} diabetes mellitus,³⁴¹ eosinophilic fasciitis,³⁴² and drugs such as clofazimine, pravastatin,³⁴³ allopurinol, hydroxyurea,^{329,344} cimetidine,³²⁹ fenofibrate, nicotinic acid, and nafoxidine.³⁴⁵ Many of the drugs interfere with lipid metabolism. An ichthyosiform contact dermatitis may follow the repeated application of antiseptic solutions containing cetrimide.³⁴⁶ There is compact orthokeratosis and/or parakeratosis without spongiosis. Cetrimide appears to act on the lipids and enzymes of the lamellar bodies.³⁴⁶ Acquired ichthyosis is sometimes seen in the recipients of bone marrow transplants.^{347,348} Acquired ichthyosis must be distinguished from asteatosis (dry skin). It may be related to an essential fatty acid deficiency in some cases.³⁴⁰

In acquired ichthyosis, there is compact orthohyperkeratosis with a reduced or absent granular layer.³²⁹

Pityriasis rotunda, which is manifested by sharply demarcated, circular, scaly patches of variable diameter and number, is probably a variant of acquired ichthyosis. It is more common in black and oriental patients than in whites. An underlying malignant neoplasm or systemic

Figure 9.8 Pityriasis rotunda. There are compact orthokeratosis and an apparent reduction in keratohyaline granules.

illness is often present.^{349–354} Pityriasis rotunda may also occur as a familial disease, suggesting that there are two types with significant prognostic differences.^{355–357} It is particularly common on the island of Sardinia, where familial cases are not uncommon, suggesting that it is a genodermatosis.³⁵⁸ Immunohistochemical studies have shown a marked reduction in filaggrin and loricrin expression in lesional skin and a reduction, on light microscopy,³⁵⁹ in keratohyaline granules, beneath a layer of compact orthokeratosis (Fig. 9.8).³⁵⁹ In a recent study, there was a complete absence of profilaggrin N-terminal domain (a proteolytic product of the protein profilaggrin) in lesional skin.³⁶⁰

REFSUM'S DISEASE

Refsum's disease (OMIM 266500), a rare autosomal recessive disorder, is characterized by ichthyosis, cerebellar ataxia, peripheral neuropathy, and retinitis pigmentosa.²⁸ The skin most resembles ichthyosis vulgaris, but the onset of scale is often delayed until adulthood. There is an inability to oxidize phytanic acid, and improvement occurs when the patient adheres to a diet free from chlorophyll, which contains phytol, the precursor of this fatty acid.²⁸ It is caused by a mutation in the gene encoding phytanoyl-CoA hydroxylase (PAHX or PHYH) at 10pter-p11.2 or the gene encoding peroxin-7 (PEX7) at 6q22-q24.³⁶¹ Decreased phytanic acid oxidation is also observed in cells lacking PEX7, so the two genes have a related function. Treatments include modification of diet,³⁶² therapeutic apheresis,³⁶³ and the intestinal lipase inhibitor orlistat.³⁶⁴ Clearing of ichthyosis in areas of skin infected by *Trichophyton rubrum* has been reported; the fungal infection resolved, but ichthyosis returned following antifungal therapy.³⁶⁵

Histopathology

A biopsy will show hyperkeratosis, a granular layer that may be increased or decreased in amount, and some acanthosis. Basal keratinocytes are vacuolated, and these stain for neutral lipid.³⁶⁶ Lipid vacuoles are also present in keratinocytes in the rare Dorfman–Chanarin syndrome, in which congenital ichthyosis is present (discussed later).³⁶⁷

Electron microscopy

There are non-membrane-bound vacuoles in the basal and suprabasal keratinocytes.³⁶⁶

OTHER ICHTHYOSIS-RELATED SYNDROMES

Ichthyosis is a feature in a number of rare syndromes. Because their histopathology resembles one of the already described forms of ichthyosis, they will be discussed only briefly.

Sjögren–Larsson syndrome

The Sjögren–Larsson syndrome (OMIM 270200) is an autosomal recessive neurocutaneous disorder characterized by the triad of congenital, pruritic ichthyosis (most resembling lamellar ichthyosis), spastic paralysis, and mental retardation.^{368–370} Other changes include short stature, kyphoscoliosis, photophobia, and a reduction in visual acuity.³⁷¹ The Mongolian spot reported in one patient appears to have been coincidental.³⁷² Sometimes the ichthyosis does not develop until the first few months of life. An enzymatic defect in fatty alcohol oxidation has been identified.^{373,374} This is due to a mutation in the *ALDH3A2* gene that codes for fatty aldehyde dehydrogenase.³⁷⁰ More than 70 mutations have been described, including one leading to partial reduction in enzyme activity.^{375–378} A prenatal diagnosis can be made by fetal skin biopsy³⁷⁹ or biochemical analysis of a cultured chorionic villus.³⁸⁰ The thickened keratin layer may still retain its basket-weave appearance.³⁸¹ At other times, it is compact. There is also acanthosis, mild papillomatosis, and a thickened granular layer. Abnormal lamellar inclusions are present in the cytoplasm of granular and horny cells by light and electron microscopy.^{370,371}

Hydration of the skin with emollients is an important first step, followed by the use of keratolytic agents, often under occlusion. Oral retinoids will assist, but they cannot be used for long periods.³⁸² Topical calcipotriol, a vitamin D analogue, is usually effective.³⁸²

'KID' syndrome

The 'KID' syndrome (OMIM 148210) comprises keratitis, ichthyosis, and deafness.^{383–394} It is rare, with fewer than 100 cases reported. It is due to a mutation in the *GJB2* (CX26) gene, which encodes the gap-junction protein connexin 26.^{395–399} It maps to chromosome 13q12.11. The Cx26 protein coordinates the exchange of molecules and ions; mutations affecting this protein cause cell death by altering intracellular calcium concentrations – important in this disease because calcium is an important regulator of epidermal differentiation.⁴⁰⁰ It is really an ectodermal dysplasia,⁴⁰¹ and the 'ichthyosis' is related to erythrokeratoderma.⁴⁰² Scarring alopecia, palmoplantar keratoderma,⁴⁰³ and susceptibility to infection⁴⁰⁴ are other clinical manifestations.⁴⁰⁵ Trichothiodystrophy-like hair abnormalities have been reported in this condition.⁴⁰⁶ An association between KID syndrome and a widespread porokeratotic eccrine and hair follicle nevus has been reported.⁴⁰⁷ Mutations in the connexin 26 gene are also associated with Vohwinkel syndrome and with sensorineural hearing loss. Various tumors, including tumors of the external root sheath, may occur in KID syndrome.^{408,409} Squamous cell carcinoma of the skin can also occur in the 'HID' syndrome (OMIM 602540), another autosomal dominant disease characterized by sensorineural deafness and spiky hyperkeratosis affecting the entire skin.⁴¹⁰ The ichthyosis in 'HID' syndrome was originally said to be of epidermolytic hyperkeratotic type (ichthyosis hystrix), giving rise to the eponym HID (*hystrix* ichthyosis and deafness).³⁷³ A recent paper makes no mention of this finding but states that the electron microscopic findings are different.⁴¹⁰ The two syndromes are allelic.

Information on the autosomal recessive form (OMIM 242150) is scanty.

Treatment with oral and/or topical acitretin has shown promising results.⁴¹¹

Conradi–Hünemann–Happle syndrome

The Conradi–Hünemann–Happle syndrome (OMIM 302960) combines punctate chondrodysplasia with ichthyosiform lesions that may be diffuse, linear following Blaschko's lines,^{412–414} or erythrodermic.^{415–417} Alopecia, nail changes, and cataracts are other manifestations. A baby girl had unilateral skin lesions that were thought to be due to mosaicism associated with X-inactivation.⁴¹⁸ It is an X-linked dominant form of chondrodysplasia punctata due to mutations in the *EBP* gene located at Xp11.23–11.22.⁴¹⁹ This gene plays a role in cholesterol biosynthesis,^{413,420} and mutations explain the elevated plasma 8(9)-cholestenol levels found in this disease.⁴²¹ A block in the same pathway occurs in the Smith–Lemli–Opitz syndrome (OMIM 270400), which also has chondrodysplasia.⁴¹⁹ Numerous different mutations have been described, but no clear genotype–phenotype correlation has emerged.^{422,423}

Mild ichthyosiform changes have been reported in two other variants of chondrodysplasia punctata.⁴¹⁷ The X-linked recessive form (OMIM 320950) is due to mutations in the arylsulfatase (*ARSE*) gene at Xp22.3, and the autosomal recessive form (OMIM 215100) is due to mutations in the *PEX7* gene encoding the peroxisome targeting signal 2 receptor on 6q24–q22. This is the same gene reported to cause one type of Refsum's disease, raising the likelihood that they are different phenotypic expressions of the same disease rather than two allelic conditions.

A skin biopsy shows hyperkeratosis, a prominent granular layer, dilated ostia of pilosebaceous follicles with keratotic plugging, dilated acrosyringia, and calcium in the stratum corneum.^{424,425} Intra-corneal calcification, often localized to keratotic follicular plugs, is diagnostic of this condition.⁴¹⁷ Parakeratosis with a diminished granular layer sometimes occurs.⁴¹⁶ Dyskeratotic cells may be present in the hair follicles.⁴¹³ Biopsy of the alopecia in one case showed perifollicular lymphocytic infiltration and granulation tissue associated with destroyed follicles; in other cases, it showed lymphocytic infiltration of sebaceous glands with sparing of their associated hair follicles.⁴²⁶

Neu–Laxova syndrome

The Neu–Laxova syndrome (OMIM 256520) is a rare, lethal, autosomal recessive ichthyosis characterized by the presence of intrauterine growth retardation, microcephaly with abnormal brain development, ichthyosis, and edema.^{427,428} A thick membrane is usually present at birth, another example of a 'collodion baby'.⁴²⁹ No gene mutations have been detected. Microscopic examination of the skin in three autopsied cases has shown hyperkeratosis, papillomatosis, and hypertrophied subcutaneous fat with resulting attenuation of subcutaneous septa and encroachment upon adnexal structures in the dermis.⁴³⁰

'CHILD' syndrome

The 'CHILD' syndrome (OMIM 308050) is an acronym for congenital hemidysplasia, ichthyosiform erythroderma (nevus), and limb defects.^{27,431–436} The 'nevus' takes the form of an erythematous plaque with a sharp border and yellowish, wax-like scaling.⁴³⁷ This is a marked affinity for body folds. As in Conradi–Hünemann–Happle syndrome, there is also an abnormality in peroxisomal function, indicating the close relationship of these two conditions.^{413,416} It is an X-linked dominant disorder that is lethal in males.^{114,438} It is due to mutations in the *NSDHL* gene on chromosome Xq28.^{437,439} The gene plays an important role in cholesterol biosynthesis. Mild expression of the phenotype is sometimes present.⁴⁴⁰ Variations include linear lesions, lesions along Blaschko's lines, and verruciform xanthomas.^{114,441} Histopathological examination reveals psoriasiform epidermal hyperplasia and, sometimes, verruciform xanthoma change.⁴³⁷ Vacuolated changes of the

granular cell layer have also been described in a recent case.⁴⁴² Squamous cell carcinoma has arisen in the affected ichthyosiform skin.⁴⁴³ Electron microscopy in one case showed abnormal lamellar granules in the stratum corneum and upper prickly cell layer.⁴⁴⁴

'IBIDS' (ichthyosis with trichothiodystrophy)

'IBIDS' (ichthyosis with trichothiodystrophy: OMIM 601675) combines ichthyosis with brittle hair, impaired intelligence, decreased fertility, and short stature.^{445,446} 'IBIDS' is used when photosensitivity is also present.⁴⁴⁷ It is associated with the defective repair of ultraviolet-induced DNA damage, as seen in xeroderma pigmentosum, but skin neoplasms have not been seen until recently.⁴⁴⁸ The brittle hair results from trichothiodystrophy. It is caused by defects in the *ERCC2* gene and, less often, the *ERCC3* gene.

'ILVASC'

'ILVASC' (OMIM 607626) is the acronym for ichthyosis, leukocyte vacuoles, alopecia, and sclerosing cholangitis. It is caused by mutations in the claudin 1 (*CLDN1*) gene located at 3q28–q29.⁴³⁹ Claudin 1 is a tight junction protein. It shares some clinical features with Dorfman–Chanarin syndrome (neutral lipid storage disease) (discussed below).

Multiple sulfatase deficiency

Multiple sulfatase deficiency (OMIM 272200) includes severe neurodegenerative disease, similar to metachromatic leukodystrophy, ichthyosis, and signs of mucopolysaccharidosis.^{28,449} It is an extremely rare autosomal recessive disorder affecting the activity of many sulfatases (aryl sulfatase A, steroid sulfatase, and several mucopolysaccharide sulfatases) – an explanation for the various clinical manifestations of this disease.⁴⁵⁰ It is due to mutations in the sulfatase modifying function 1 (*SUMF-1*) gene at 3p26–p25.⁴³⁹ Not surprisingly, the ichthyosis has some features of X-linked ichthyosis. If the ichthyosis is mild, treatment with emollients will suffice.⁴⁵¹

'MAUIE' syndrome

The 'MAUIE' syndrome consists of micropinnae, alopecia universalis, congenital ichthyosis, and ectropion. The early development of skin cancer has been reported in this syndrome.⁴⁵² It is not listed on the OMIM database.

Neutral lipid storage disease (Dorfman–Chanarin syndrome)

Neutral lipid storage disease (Dorfman–Chanarin syndrome; OMIM 275630), in which neutral lipid accumulates in the cytoplasm of many cells of the body, combines fatty liver with muscular dystrophy and nonbullous ichthyosiform erythroderma.^{28,453,454} Other patterns of ichthyosis have been described.^{455,456} It is an autosomal recessive disorder in which a defect of acylglycerol recycling from triacylglycerol to phospholipid has been identified in fibroblasts.⁴⁵⁷ It is due to mutations in the *CGI-58* (*ABHD5*) gene located on 3p21.^{458–460} An excess of triacylglycerol accumulates in most cells.⁴⁶¹ Studies suggest that a deficiency of acylceramide contributes to an epidermal permeability barrier abnormality that may, in turn, promote the hyperkeratosis that characterizes this syndrome.⁴⁶² Lipid droplets are found within leukocytes (Jordans' anomaly). A skin biopsy shows hyperkeratosis, mild acanthosis, and discrete vacuolation of basal keratinocytes, sweat glands, and sweat ducts.⁴⁶³ The vacuoles contain lipid. Another case reported hyperkeratosis and a diminished granular cell layer, resembling ichthyosis vulgaris.⁴⁶⁴

Shwachman syndrome

Shwachman syndrome (Shwachman–Diamond syndrome; OMIM 260400) combines pancreatic insufficiency and bone marrow dysfunction with xerosis and/or ichthyosis.^{434,465} It is due to mutations in the *SBDS* gene at 7q11.

Other named and unnamed associations have been described.^{27,466–468} One of these is ichthyosis associated with the ARC syndrome (arthrogryposis, renal tubular dysfunction, and cholestasis; OMIM 208085) due to a mutation in the *VPS33B* gene on chromosome 15q26.1.^{469,470} Defective lamellar granule secretion has been described in this condition.⁴⁷⁰ Another is the association of ichthyosis, follicular atrophoderma, hypotrichosis, and woolly hair (OMIM 602400).⁴⁷¹

PALMOPLANTAR KERATODERMAS AND RELATED CONDITIONS

In addition to the group of disorders usually categorized as the palmo-plantar keratodermas, there are several rare genodermatoses that are usually regarded as discrete entities in which palmo-plantar keratoderma is a major clinicopathological feature. These disorders include hidrotic ectodermal dysplasia (see p. 317), acrokeratoelastoidosis (see p. 298), pachyonychia congenita (see p. 298), tyrosinosis (see p. 297), and pachydermoperiostosis (see p. 359). Keratoderma may also occur as a manifestation of certain inflammatory dermatoses, such as pityriasis rubra pilaris, Reiter's disease, psoriasis, Darier's disease, and as a paraneoplastic manifestation.⁴⁷² These conditions are not considered further in this chapter.

Palmo-plantar keratoderma may result from mutations in keratin genes (pachyonychia congenita and epidermolytic hyperkeratosis of palms and soles) or in the genes regulating the desmosomal cadherins (plakophilin 1, plakoglobin, desmoplakin, desmoglein 1, and desmocollin 3).⁴⁷³

PALMOPLANTAR KERATODERMAS

The palmo-plantar keratodermas are a heterogeneous group of congenital and acquired disorders of keratinization, characterized by diffuse or localized hyperkeratosis of the palms and soles, sometimes accompanied by other ectodermal abnormalities.^{474,475} Another classification system has also been proposed: the four major categories are diffuse, focal/circumscribed, and punctate palmo-plantar keratodermas and the palmo-plantar ectodermal dysplasias. More than 20 subtypes have been described in the latter category.⁴⁷⁶ In one Indian study, the focal/circumscribed group was the most common type of palmo-plantar keratoderma.⁴⁷⁷ Categorization has been made on the basis of their mode of inheritance, sites of involvement, and associated abnormalities.⁴⁷⁸ The autosomal recessive types are usually the most severe and include mal de Meleda, Papillon–Lefèvre syndrome, some mutilating variants, and a variant associated with generalized ichthyosis.⁴⁷⁹ The other hereditary forms are autosomal dominant, although sporadic cases of most syndromes occur.⁴⁸⁰

Another feature used to distinguish the various subtypes of keratoderma is the presence of hyperkeratosis beyond the palms and soles. These 'transgrediens' lesions occur in the Olmsted, Greither, Vohwinkel, and mal de Meleda types.⁴⁸¹ Onset of most keratodermas is at birth or in early infancy, but later onset is seen in the punctate and acquired forms. New syndromes continue to be reported or recognized.^{482,483} In one of these, palmo-plantar keratoderma is associated with large ears, hypopigmented hair, and frontal skull bossing.⁴⁸⁴ In another type, the Bothnian type (OMIM 600231), found in northern Sweden, the gene maps to 12q11–q13.⁴³⁹ In yet another, a non-epidermolytic palmo-plantar keratoderma is associated with sen-

sorineural deafness and a mutation in the mitochondrial genome (mtDNA).^{485,486} There are at least two genotypic variants of palmo-plantar keratoderma with deafness. One is due to a mutation in the connexin 26 gene (*GJB2*) at 13q11–q12 (OMIM 148350), and the other is due to the mitochondrial mutation just mentioned. It has consistently involved an A7445G point mutation (OMIM '590080').⁴⁸⁶ In *palmo-plantar keratoderma with anogenital leukokeratosis*, an absence of K6 and K16 has been detected.⁴⁸⁷ No keratin or genetic studies were done on the case with oral leukokeratosis and recurring cutaneous horns of the lip.⁴⁸⁸ In the *Schöpf–Schulz–Passarge* syndrome (OMIM 224750), there are associated apocrine hidrocystomas, hypodontia, hypotrichosis, and hypoplastic nails.^{489,490}

Brief mention will be made of the important clinical features of the various keratodermas.

Unna–Thost syndrome

Unna–Thost syndrome (OMIM 600962) usually presents in the first few months of life.^{491,492} Late onset has been recorded.^{477,493} Deafness is sometimes present,⁴⁹⁴ whereas acrocyanosis and total anomalous pulmonary venous drainage are rare associations.^{495,496} Atopic dermatitis is another association.⁴⁹⁷ Verrucous carcinoma has been reported in one case.⁴⁹⁸ The syndrome may not be as common as once thought, because of the inclusion of cases of Vörner's syndrome with which it is clinically, but not histologically, identical.⁴⁹⁹ This epidermolytic hyperkeratotic type (OMIM 144200) might best be kept separate from other cases. On the other hand, apparently the family originally described by Thost showed histopathologic features of epidermolytic hyperkeratosis, similar to the changes in Vörner's palmo-plantar keratoderma, and these patients were also found to have mutations in the same part of the keratin 9 gene. These findings suggest to some that Unna–Thost and Vörner palmo-plantar keratoderma may be the same entity.⁵⁰⁰ Two variants of Unna–Thost syndrome have been reported. One involves *KRT1*, which maps to the type II keratin cluster on chromosome 12q13,⁵⁰¹ and the other involves *KRT16* on 17q12–q21.

Greither's syndrome

In this 'transgrediens' form (hyperkeratosis beyond the palms and soles), the elbows and knees may be more involved than the palms and soles.^{473,502} It also involves the skin over the Achilles tendon.⁵⁰³ It is associated with hyperhidrosis. The inheritance is autosomal dominant with reduced penetrance.⁵⁰⁴ The gene has not been identified, but families have been described in whom the same dominant missense mutation gave rise to the amino acid change N188S in keratin 1.⁵⁰³ Histological changes are nonspecific with hyperkeratosis and acanthosis,⁵⁰⁵ although epidermolytic changes involving the granular cell layer have been described.

Olmsted's syndrome

Periorificial keratoderma and oral leukokeratosis accompany the transgrediens palmo-plantar keratoderma, which is often mutilating.^{481,506–512} Alopecia and perianal keratotic plaques are sometimes present.^{513,514} This syndrome has been reported in twins.⁵¹⁵ Most cases are sporadic.⁵¹⁶ A closely related entity with corneal epithelial dysplasia has been reported.⁵¹⁷ Abnormal expression of keratins 5 and 14 appears to be the underlying disorder,⁵¹⁸ this remains to be confirmed. Mutations have recently been found in the transient receptor potential cation channel, subfamily V, member 3 (*TRPV3*) gene, which may have important functions in keratinization and hair growth.⁵¹⁹ Plantar squamous cell carcinomas sometimes develop.⁵²⁰ Evidence for immune dysregulation has included frequent cutaneous infections, hyper IgE, and persistent eosinophilia.⁵²¹

The histopathological findings on palmar skin include psoriasiform hyperplasia, hypogranulosis, and alternating parakeratosis and orthohyperkeratosis.⁵¹³ In another case, the findings were simply described as hyperkeratosis, acanthosis, and a mild perivascular dermal infiltrate.⁵²²

Emollients and keratolytics have been used to treat the disease.⁵²³ Retinoids provide temporary relief.⁵¹¹ Excision and grafting has also been used.⁵²⁴

Vohwinkel's syndrome

Vohwinkel's syndrome is a family of genodermatoses that exhibits clinical and genetic heterogeneity.⁵²⁵ There is a variant with deafness (OMIM 124500) and another with ichthyosis (OMIM 604117). In both forms, there is a honeycombing pattern of keratoderma with starfish-shaped keratoses on the dorsa of the digits and linear keratoses on the knees and elbows.^{526–529} Ainhum-like constriction bands develop, leading to gangrene of the digits in adolescence.^{527,530–532} A recessive variant is associated with ectodermal dysplasia.⁵³³ Congenital deaf-mutism is a rare association.⁵³⁴ The subset of patients with mutilating keratoderma and sensorineural hearing loss (OMIM 124500) has a mutation in the *GJB2* gene on chromosome 13q11–q12, which encodes the gap junction protein connexin 26.⁵³⁵ The subset of patients with Vohwinkel's keratoderma and an associated ichthyosiform dermatosis (OMIM 604117) has a mutation in the loricrin gene (*LOR*) on chromosome 1q21.^{525,536,537} The mutant loricrin is translocated into the nucleus of the keratinocyte and not into the cornified cell envelope as might be expected.²⁸³ This form of the disease is now known as loricrin keratoderma.⁵³⁸ It can be summarized as 'honeycomb palmoplantar keratoderma with ichthyosis'.⁵³⁸

Epidermolytic palmoplantar keratoderma (Vörner's syndrome)

The term 'epidermolytic palmoplantar keratoderma' (OMIM 144200) is widely used for this variant, reflecting the histological changes.^{539–546} It is clinically indistinguishable from the Unna–Thost variant, the relationship to which was previously briefly discussed. It has early onset and thick yellowish hyperkeratosis often with an erythematous border.^{547,548} A kindred with associated internal malignancy has been reported.⁵⁴⁹ Mutations of keratin 9 (*KRT9*), which is specifically found in the suprabasal keratinocytes of palmoplantar epidermis and outer root sheath epithelium, have been found in this variant.^{547,550–562} A variant with a novel *KRT9* mutation has been associated with knuckle pad-like lesions and digital mutilations.⁵⁶³ At least 15 mutations in this gene have been reported.^{564,565} It is linked to chromosome 17q12–q21.⁵⁶⁶ Mutations in the keratin 1 (*KRT1*) gene are found in epidermolytic hyperkeratosis (bullous ichthyosiform erythroderma; OMIM 113800), which may also be associated with a palmoplantar keratoderma (see p. 287).⁵⁶⁷ Other kindreds with mutations in *KRT1* have presented with only palmoplantar keratoderma and no generalized disease, but in these cases the hyperkeratosis has either extended onto the proximal wrist flexure⁵⁶⁸ or involved other sites focally.^{160,212} This is the PS-1 variant of epidermolytic hyperkeratosis. It responds poorly to retinoids.¹⁶⁰

Epidermolytic palmoplantar keratoderma has occurred in several members of a family with Ehlers–Danlos syndrome, type III.⁵⁶⁹ The genes for these two conditions are not closely linked. Focal variants have been described with the histology of epidermolytic hyperkeratosis. In one such case (OMIM 148730), focal palmoplantar keratoderma was associated with leukokeratosis.⁵⁷⁰ Another variant is the unilateral palmoplantar verrucous nevus that represents mosaicism for a keratin 16 mutation.⁵⁷¹

Howel–Evans syndrome

Howel–Evans syndrome (tylosis with esophageal cancer; OMIM 148500) comprises palmoplantar keratoderma and esophageal cancer.

The palmoplantar keratoderma begins early in life, and affected family members develop a squamous cell carcinoma of the esophagus in middle adult life.⁵⁷² The gene has been linked to chromosome 17q25, which is distal to the type I keratin gene cluster.⁴⁷⁶ Several candidate genes have been suggested, including envoplakin⁴³⁹ and *DMC1*. Until identified and fully characterized, the gene for Howel–Evans syndrome has been called *TOC*. Some authors distinguish two types (A and B) depending on the age of onset.⁵⁷³ Squamous cell carcinoma sometimes develops in the thickened skin of the palms.⁵⁷⁴ Interestingly, palmoplantar keratoderma has been reported in one patient with postcorrosive stricture of the esophagus.⁵⁷⁵

Papillon–Lefèvre syndrome

In Papillon–Lefèvre syndrome (OMIM 245000), an autosomal recessive condition with a prevalence of 1–4 per 1 million, there is periodontitis accompanied by premature loss of the deciduous and permanent teeth.^{576–580} It is a type IV palmoplantar keratoderma, along with the Haim–Munk syndrome. They differ from the other three types by the presence of early onset periodontitis and their autosomal recessive inheritance.⁵⁸¹ Involvement of the elbows and knees and calcification of the choroid plexus may occur.^{582,583} It has been associated with pseudoainhum of the thumb.⁵⁸⁴ Pyogenic infections also occur in this disease.⁵⁸⁵

This condition is caused by a mutation in the cathepsin C gene (*CTSC*) located at chromosome 11q14.1–q14.3.^{586–589} The phenotypically related Haim–Munk syndrome is an allelic mutation.⁵⁹⁰ There may be mild phenotypic expression of the disease with late onset and mild skin or periodontal disease.⁵⁹¹ Elevated IgE levels were found in a Chinese patient who also had compound mutations of cathepsin C.⁵⁹² In one late-onset case, no mutations in the cathepsin C gene were found, suggesting the possibility of another genetic cause.⁵⁹³ The severity of the periodontal disease does not correlate with the severity of the skin lesions.⁵⁹⁴ This syndrome has been reported in two families with oculocutaneous albinism.⁵⁹⁵ The genes for these two conditions are closely situated on chromosome 11q14.⁵⁹⁵

Periodontitis is also present in the 'HOPP' syndrome (*hypotrichosis, acro-osteolysis, palmoplantar keratoderma, periodontitis*; OMIM 607658), but there is no mutation in the cathepsin C gene.⁵⁹⁶ The original report described the keratoderma as being striate.⁵⁹⁷

Treatment with oral acitretin has been effective in controlling the disease.^{598,599}

Haim–Munk syndrome

The Haim–Munk syndrome (OMIM 245010), which is allelic to the Papillon–Lefèvre syndrome, is an extremely rare autosomal recessive condition caused by mutations in the cathepsin C gene (*CTSC*) located at chromosome 11q14.1–q14.3.⁵⁸⁹ It is characterized by palmoplantar hyperkeratosis, severe early onset periodontitis, pes planus, arachnodactyly, and acro-osteolysis.^{581,589}

Mal de Meleda

Mal de Meleda (OMIM 248300) – a rare, autosomal recessive variant of palmoplantar keratoderma – was first described in families living on the small island of Meleda in the Adriatic Sea.^{600,601} The responsible gene, *ARS B*, which encodes SLURP-1 (secreted mammalian Ly-6/uPAR related protein-1), is localized to 8qter.^{602–606} A founder effect for the W15R mutation in the SLURP1 gene in mal de Meleda patients has been suggested in the western European population.⁶⁰⁷ SLURP-1 is an agonist to the nicotinic acetylcholine receptor, the signaling of which is involved in the regulation of T-cell function. Accordingly, studies suggest that patients homozygous for the SLURP-1 G86R mutation may have defective T-cell activation.⁶⁰⁸ Onset is at birth or

in infancy. Lesions may extend from the palms and soles onto the dorsum of the hands and feet, respectively, although there is a sharp 'cutoff' at the wrists and ankles (transgrediens type).^{600,609-612} Pseudoainhum is a rare complication.⁶¹³ In one case, pigmented macules were present in the involved areas of palmoplantar keratoderma.⁶¹⁴ Hyperhidrosis leads to severe malodorous maceration.⁴⁷⁸ **Palmoplantar keratoderma of Sybert** is clinically similar, but its inheritance is autosomal dominant; only one family has been reported.⁴⁹⁹ **Nagashima-type palmoplantar keratoderma**, reported from Japan, is an autosomal recessive, transgressive, and nonprogressive palmoplantar keratoderma.^{615,616} Although similar to mal de Meleda, there were no mutations in the SLURP-1 gene.⁶¹⁶

Mal de Naxos (Naxos disease)

This condition (OMIM 601214) is due to a mutation in the plakoglobin gene (*JUP*), located at 17q21. It was first reported in families on the Greek island of Naxos. It is characterized by palmoplantar keratoderma, woolly hair, and arrhythmic cardiomyopathy.^{617,618}

Carvajal syndrome

Carvajal syndrome (OMIM 605676) has similar phenotypic features to Naxos disease. It is caused by mutations in the gene encoding desmoplakin (*DSP*), which maps to 6p24.⁶¹⁹ It is characterized by palmoplantar keratoderma and woolly hair, but the accompanying cardiomyopathy is of dilated type. A similar mutation is seen in type II striate palmoplantar keratoderma (discussed later). Oligo/hypodontia has also been reported in this syndrome.⁶²⁰ In a recent case, mutations in the desmoplakin or plakoglobin genes were not identified; this suggests that other genes may be involved in some cases, although gene rearrangement or deletions of a single exon could not be excluded.⁶²¹

Gamborg Nielsen keratoderma

Two Swedish families have been reported with very thick hyperkeratotic plaques on the dorsal aspect of the fingers.⁴⁹⁹

Palmoplantar keratoderma with sclerodactyly (Huriez syndrome)

This syndrome (OMIM 610644) is an extremely rare autosomal disease characterized by palmoplantar keratoderma, sclerodactyly (described in some publications as scleroatrophy), hypohidrosis, nail anomalies, and squamous cell carcinomas of affected skin.^{499,622-625} Additional features include dental anomalies, hypogenitalism, telangiectasia of the lips, flexor contractures of the little finger, and poikiloderma-like lesions on the nose.^{626,627} There is a mutation in the gene (*RSPO1*) encoding R-spondin-1. The related R-spondin gene *RSPO4* produces autosomal recessive congenital anonychia.⁶²⁸⁻⁶³⁰

Punctate palmoplantar keratoderma

Punctate palmoplantar keratoderma (OMIM 148600) is a rare, localized, hereditary variant of palmoplantar keratoderma characterized by discrete, hard, keratotic plugs arising in normal skin.^{631,632} It is also termed type 1A punctate palmoplantar keratoderma of Buschke-Fisher-Brauer (the other types are type 2, punctate porokeratotic keratoderma, and type 3, acrokeratoelastoidosis or focal acral hyperkeratosis). A subset with verrucoid lesions has been reported.⁶³³ Another variant is confined to the palmar and digital creases.⁶³⁴ It is more common in black people.⁶³⁵⁻⁶³⁸ The punctate keratoses coalesce into a more diffuse pattern over the pressure points on the soles.^{639,640} The plugs form again if removed. Wood's light excites white fluorescence in lesions of this condition.⁶⁴¹ Onset is usually in adolescence,

but it may be much later.⁶⁴² An underlying malignancy has been present or developed subsequently in a few cases.^{643,644} Widespread lentigo simplex was present in one case.⁶⁴⁵ Punctate lesions, which are characterized histologically by a cornoid lamella, are best classified as punctate porokeratotic keratoderma;⁶⁴⁶ they are clinically indistinguishable from the other punctate forms.^{633,636-638,643,647,648} The term 'spiny keratoderma' has also been used for this type.^{649,650} Cole disease, in which hypopigmentation accompanies the punctate keratoderma, is probably a variant.⁶⁵¹ In 2005, a gene, localized to 15q22.2-q22.31, was identified in a four-generation Chinese family.⁶³⁹ Subsequently, the molecular basis of this disease was established as a heterozygous mutation of the *AAGAB* gene on chromosome 15q22.⁶⁵²⁻⁶⁵⁴ Topical agents such as keratolytic ointments, retinoids, and vitamin D analogues result in minor improvement in the condition. Combination therapy with 40% salicylic acid ointment and oral acitretin produced good results in one patient.⁵⁸⁰ Acitretin alone has also been used.⁶⁵⁵ Other therapies used include mechanical debridement, salicylic acid, topical tazarotene gel, topical fluorouracil, and surgical excision.⁶⁵⁶

Striate palmoplantar keratoderma

Striate palmoplantar keratoderma is a very rare form of palmoplantar keratoderma characterized by linear hyperkeratotic streaks along the volar surface of the fingers and focal keratoderma over the soles. It is a form of circumscribed keratoderma (see later). It has been reported in monozygotic twins.⁶⁵⁷ Sporadic cases also occur.⁶⁵⁸ Three types have been identified:

- Type I (OMIM 148700) due to mutations in the desmoglein 1 gene (*DSG1*) on 18q12.1-q12.2
- Type II (OMIM 125647) due to mutations in the desmoplakin gene (*DSP*) at 6p24
- Type III (OMIM 607654) due to mutations in the keratin 1 gene (*KRT1*) at 12q13.^{439,659,660}

Both desmoglein 1 and desmoplakin are critical components of the desmosomal plaque and associated keratin intermediate filaments in the upper epidermis.^{618,661} Mutations of the tail domain of keratin 1 have been shown to affect the function of the plaque during cornification.⁶⁶⁰ Disadhesion and partial acantholysis of keratinocytes in the spinous and granular cell layers have been reported in patients with *DSG1* mutations.⁶⁶² In a recent case suspected of being type I disease, microscopic features included orthokeratosis, hypergranulosis, and acanthosis, together with widening of intercellular spaces between keratinocytes and condensation of cytoplasm in these cells.⁶⁶³ One case of striate palmoplantar keratoderma was apparently related to antiretroviral therapy for HIV disease. On several occasions, the keratoderma improved upon discontinuation of this therapy only to recur once it was restarted. Microscopically, widening of intercellular spaces between keratinocytes was not observed in this case.⁶⁶⁴

Circumscribed keratoderma

Focal areas of thickening, sometimes tender, may develop on the palms and soles.⁶⁶⁵ Some have an autosomal recessive inheritance. This is a clinically heterogeneous group,⁶⁶⁵ which includes the conditions of *hereditary painful callosities* (*keratosis palmoplantis nummularis*)⁶⁶⁶⁻⁶⁶⁸ and *keratoderma palmoplantis striata* (*striate palmoplantar keratoderma*).⁶⁶⁹⁻⁶⁷¹ This condition was previously considered. Corneal dystrophy has been present in some circumscribed variants.⁶⁶⁵ Localized hypertrophy of the skin of the soles and palms can occur in the *Proteus syndrome*, a rare disorder in which the major manifestations are skeletal overgrowth, digital hypertrophy, exostoses of the skull, subcutaneous lipomas, and, sometimes, epidermal nevi.⁶⁷² Tyrosinemia type II (Richner-Hanhart syndrome) also has localized lesions (discussed later). Focal palmoplantar callosities have been reported in a

patient with non-Herlitz junctional epidermolysis bullosa.⁶⁷³ All of these circumscribed variants have been classified as ‘nummular hereditary palmoplantar keratodermas’,⁴⁹⁹ a term that appears unsuitable with regard to the morphological diversity of the lesions. A variant of epidermolytic palmoplantar keratoderma, localized to the palm and sole of one side of the body and following Blaschko’s lines, has been reported. The term ‘unilateral palmoplantar verrucous nevus’ was suggested for this mosaic mutation in *KRT16*.⁵⁷¹ Its histology was that of epidermolytic hyperkeratosis.

Acquired keratoderma

Palmoplantar keratoderma or discrete keratotic lesions may rarely develop in cases of myxedema,^{674–676} psoriasis,⁶⁷⁷ lichen planus, pityriasis rubra pilaris,⁶⁷⁸ mycosis fungoides,⁶⁷⁹ lymphoma,⁶⁸⁰ multiple myeloma,⁶⁸¹ and internal cancers,⁶⁸² following exposure to arsenic and after menopause or following bilateral oophorectomy (keratoderma climactericum).⁶⁸³ It has also been reported in a patient with a pemphigus-like immunobullous disease associated with antibodies to desmocollin 3.⁴⁷³ Livedoid palmoplantar keratoderma has been reported in a patient with systemic lupus erythematosus.³³⁶ Rugose lesions of the palms may occur in association with acanthosis nigricans, so-called ‘tripe palms’ (pachydermatoglyphy);^{684–686} in a few instances, this condition has been reported in association with a cancer, without concurrent acanthosis nigricans.^{687,688} Transforming growth factor- α has been incriminated in the pathogenesis of this paraneoplastic change.⁶⁸⁹ Keratoderma has been described in patients with AIDS following the infusion of glucan, which was used as an immunostimulant.⁶⁹⁰ Palmoplantar keratoderma has also followed the use of tegafur, in the treatment of an adenocarcinoma of the colon⁶⁹¹ and one of the gallbladder.⁶⁹² There was a preceding acral erythema. Similar side effects have been reported with fluorouracil, a closely related drug.⁶⁹¹ Exposure to herbicides was implicated in another case.⁶⁹³ Acquired punctate lesions on the palms and soles may follow dioxin intoxication.⁶⁹⁴ Other drugs that may cause this condition include imatinib,⁶⁹⁵ capecitabine,⁶⁹⁶ and venlafaxine.⁶⁹⁷

Finally, mention is made of a type of callus that is a computer-related occupational dermatosis resulting from friction and pressure on the hand secondary to computer mouse use. It has been called ‘mousing callus’.⁶⁹⁸

Aquagenic acrokeratoderma

Aquagenic acrokeratoderma (transient reactive papulotranslucent acrokeratoderma, aquagenic palmoplantar keratoderma, and aquagenic syringeal acrokeratoderma) was described by English and McCollough in 1996.⁶⁹⁹ It is characterized by the rapid development of transient whitish, usually symmetric, hypopigmented flat-topped papules and plaques on palmar or plantar⁷⁰⁰ skin after exposure to water or sweating.^{699,701–705} Sometimes lesions develop on the dorsal aspect of the fingers,⁷⁰⁶ and a case restricted to the fingers has also been reported.⁷⁰⁷ Unilateral cases have been reported.^{708,709} Eccrine duct prominence is sometimes observed in these lesions, which arise within a few minutes after immersion (‘hands-in-the-bucket’ sign).⁷¹⁰ They may be asymptomatic or accompanied by a pruritic or burning sensation.⁷¹¹ They resolve after variable drying periods.⁷¹² Markedly enlarged sweat duct pores are identified on dermoscopic examination.⁷¹³

It involves predominantly young females,⁷¹⁴ but cases in males have been reported.^{710,711,715,716} Familial cases have been recorded.^{717,718} Most cases are transient and reactive.^{703,719} It has been reported in patients with cystic fibrosis,⁷¹¹ cystic fibrosis carriers,⁷²⁰ asthma, allergic rhinitis, congenital cardiomyopathy,⁷¹⁶ palmar erythema, hyperhidrosis,⁷⁰⁰ melanoma, and after the ingestion of aspirin⁷⁰⁸ or rofecoxib.⁷²¹ Sodium retention in the skin may be a mechanism in some cases.⁷²¹ Reduced activity of transglutaminase resulting in alterations in the cornified

cell envelope and barrier function is another possible pathogenic mechanism.

Spontaneous amelioration occurs in some patients. Topical aluminum chloride or 12% aluminum lactate cream⁷⁰³ has produced a remarkable response in 1 week.^{705,714}

Histopathology

The cornified layer has a spongy appearance.⁷¹⁴ There is dilatation of the intraepidermal eccrine ducts and some hyperkeratosis around these dilated ducts.⁷¹⁰ A distinctive crenulated appearance has been reported in the eccrine coil.⁷²² There is aberrant staining for aquaporin 5 (AQP5) in the sweat glands, suggesting that the condition stems from dysregulation of sweating.⁷²³

Interdigital keratoderma

The rare interdigital variant is characterized by a symmetrical keratoderma localized to the interdigital spaces of the fingers.⁷²⁴

Histopathology of palmoplantar keratodermas

The *diffuse forms* show prominent orthokeratotic hyperkeratosis, with variable amounts of focal parakeratosis. The granular layer is often thickened. There is also some acanthosis of the epidermis and a sparse, superficial, perivascular infiltrate of chronic inflammatory cells. In Greither’s syndrome, there are circumscribed foci of orthokeratotic hyperkeratosis located on delled areas of the epidermis (Fig. 9.9).⁵⁰⁴ In a case of Olmsted’s syndrome, there was massive hyperkeratosis and a reduced to absent granular layer.⁷²⁵ In the Huriez syndrome, there is massive hyperkeratosis, marked acanthosis, and hypergranulosis.⁷²⁶ The scleroatrophic areas show thickening of the dermal collagen bundles.⁷²⁶

The *epidermolytic form* shows epidermolytic hyperkeratosis. This tissue reaction is described on page 301.

The *punctate forms* show a dense, homogeneous keratin plug that often results in an undulating appearance in the epidermis.^{642,647} There is usually a slight depression in the epidermis beneath the plug (Fig. 9.10).⁶⁴⁷ Punctate cases with a parakeratotic plug are best classified as punctate prokeratotic keratoderma (Figs. 9.11 and 9.12).⁷²⁷ Focal acantholytic dyskeratosis was present in the punctate lesions in one reported case.⁷²⁸

Striate keratodermas may show widening of intercellular spaces within the spinous layers of the epidermis. In *hereditary callosities with blisters*, there is intraepidermal vesiculation with cytolysis of

Figure 9.9 Keratoderma in Greither’s syndrome. There are marked hyperkeratosis and acanthosis. In this example, vacuolated changes can be identified between the granular cell layer and the hyperkeratotic stratum corneum. (H&E)

Figure 9.10 Punctate keratoderma. There is slight depression of the epidermis beneath a keratin plug. There is a pit in the adjacent stratum corneum. (H&E)

Figure 9.11 Punctate porokeratotic (spiny) keratoderma. A wide cornoid lamella is present towards one edge of the field. (H & E) (Photograph kindly supplied by Dr. J. J. Sullivan.)

keratinocytes and clumping of tonofilaments.⁶⁶⁶ The changes resemble those seen in pachyonychia congenita (see p. 298). In other cases, epidermolytic hyperkeratosis has been present.⁶⁶⁸

Electron microscopy

Ultrastructural studies have not shown consistent abnormalities. It seems that the normal association of filaggrin and keratin filaments does not occur in the stratum corneum.⁴⁷⁴ Nucleolar hypertrophy has been noted in the punctate form.⁶⁴⁷ Ultrastructural studies of the Papillon-Lefèvre syndrome have shown lipid-like vacuoles in corneocytes, abnormally shaped keratohyaline granules, and a reduction in tonofilaments.⁷²⁹ Vacuoles and many membrane-coating granules were seen in corneocytes in Vohwinkel's syndrome.⁵²⁹

OCULOCUTANEOUS TYROSINOSIS

Oculocutaneous tyrosinosis (OMIM 276600), also known as tyrosinemia II and the Richner-Hanhart syndrome, is an extremely rare, autosomal recessive genodermatosis caused by a deficiency of hepatic

Figure 9.12 Punctate porokeratotic (spiny) keratoderma. The granular layer is absent beneath the parakeratotic zone. (H&E) (Photograph kindly supplied by Dr. J. J. Sullivan.)

tyrosine aminotransferase (tyrosine transaminase).⁷³⁰⁻⁷³⁵ The gene is located at 16q22.1-q22.3. It is usually characterized by corneal ulcerations and painful keratotic lesions on the palms and soles, but ocular lesions have been absent in some kindreds.⁷³⁶ The palmoplantar lesions vary from fine 1- or 2-mm keratoses to linear or diffuse keratotic thickenings.^{734,737} Erosions and blisters have also been reported.⁷³⁸⁻⁷⁴⁰ Mental retardation is often present. The condition is treated by a dietary restriction of tyrosine and phenylalanine. If started early, mental retardation may be avoided.⁷³⁹

Histopathology⁷³¹

The palmoplantar lesions show prominent hyperkeratosis and parakeratosis with variable epidermal hyperplasia. Scattered mitoses and multinucleate keratinocytes may be present.^{741,742} Epidermolytic hyperkeratosis and intraepidermal bulla formation have been present in some families.⁷³⁸

Electron microscopy

Lipid-like granules have been noted in the upper epidermis.⁷⁴³ An increase in tonofibrils and keratohyalin has also been seen in affected skin.⁷⁴¹

ACROKERTOELASTOIDOSIS

Acrokeratoelastoidosis (Costa's papular acrokeratosis; OMIM 101850)⁷⁴⁴ is a rare variant of palmoplantar keratoderma that occurs both sporadically and as an autosomal dominant genodermatosis.⁷⁴⁵⁻⁷⁴⁷ No gene has been implicated, although early linkage studies suggested the *ACPI* gene; another study suggested a gene on chromosome 2.⁷⁴⁸ This has never been confirmed. There appears to be some variability in the morphological expression of the disease.^{749,750} Its onset is in childhood or early adult life, and there is a female predominance. There are multiple, small (2–5 mm in diameter), firm, translucent, asymptomatic papules that are most numerous along the junction of the dorsal and palmar or plantar surfaces of the hands and feet, respectively.^{751,752} Larger plaques also develop by coalescence of the papules.⁷⁵³ They may be localized to the sides of the fingers, particularly the inner side of the thumb and the adjoining index finger. In this situation, they resemble clinically the lesions seen in collagenous and elastotic plaques of the hands (see p. 394), an acquired entity that is found predominantly in males older than age 50 years and that results from trauma and actinic damage.⁷⁴⁴ In acrokeratoelastoidosis, there may also be a mild diffuse hyperkeratosis of the palms and soles; this was a prominent feature in one report.⁷⁵⁴ There may also be isolated lesions over interphalangeal joints and elsewhere on the dorsum of the hands and feet.⁷⁵⁵ A variant of acrokeratoelastoidosis has been found on the palms in systemic scleroderma.⁷⁵⁶ Unilateral disease has been rarely reported.⁷⁵⁷

The treatment is a matter of debate. No curative treatment has been reported to date.⁷⁵⁸ Options include topical keratolytics, retinoids, or corticosteroids. Systemic immunosuppressive therapy with prednisone or methotrexate has also been used.⁷⁵⁸ Cryosurgery has been unsuccessful, whereas the erbium:YAG laser has produced slight improvement.⁷⁵⁸

Histopathology⁷⁵⁹

There may be slight hyperkeratosis with a shallow depression in the underlying epidermis, which shows a prominent granular layer and mild acanthosis. The dermis may be normal or slightly thickened. The elastic fibers are decreased in number, thin, and somewhat fragmented in the mid and deep reticular dermis (Fig. 9.13).⁷⁶⁰ In some cases, the elastic fibers are coarse and fragmented.⁷⁵⁵ Cases have been reported with no light microscopic changes in the dermis.⁷⁴⁵ The group that lacks elastorrhexis has been designated '**focal acral hyperkeratosis**'.⁷⁶¹⁻⁷⁶³ Their relationship is controversial, particularly because the epidermal changes of focal acral hyperkeratosis are caused by increased

proliferation and differentiation of lesional keratinocytes.⁷⁶⁴ The ortho-hyperkeratosis overlies a clavus-like depression of the epidermis and prominent hypergranulosis.⁷⁶⁵

Electron microscopy

In acrokeratoelastoidosis, there is disaggregation of elastic fibers with fragmentation of the microfibrils.⁷⁴⁵ In one report, the fibroblasts contained dense granules in the cytoplasm and there was an absence of extracellular fibers, leading to the hypothesis that there was a block in the synthesis of elastic fibers by the fibroblasts.⁷⁶⁶

Differential diagnosis

The differential diagnosis of circumscribed hyperkeratotic lesions includes corn (clavus), which often has some parakeratosis and lacks underlying elastic fiber abnormalities. There is also a group of disorders that are classified as *marginal papular acrokeratodermas*, which have been summarized in a paper by Rongioletti and colleagues.⁷⁶⁷ In addition to acrokeratoelastoidosis and focal acral hyperkeratosis, the other disorders are **acrokeratoelastoidosis of Matthews and Harman**, **mosaic acral keratosis**, **hereditary papulotranslucent acrokeratoderma**, **acrokeratoderma hereditarium punctatum**, **keratoelastoidosis marginalis**, and **digital papular calcinosis**. The previously mentioned **degenerative collagenous and elastotic plaques of the hands** has also been included in this grouping. A number of these are obscure, rarely reported, and not clearly different from acrokeratoelastoidosis or focal acral hyperkeratosis. Degenerative collagenous and elastotic plaques of the hands and keratoelastoidosis marginalis are certainly related to chronic solar injury (with trauma possibly playing a role in the latter). Some patients with mosaic acral keratoses have also been found to have palmoplantar keratosis and keratotic papules in locations other than the hands and feet.

PACHYONYCHIA CONGENITA

Pachyonychia congenita is a rare genodermatosis in which symmetrical, hard thickening of the nails of the fingers and toes is the most striking and consistent feature.⁷⁶⁸⁻⁷⁷⁰ Various other abnormalities of keratinization are usually present.⁷⁷¹ These include palmar and plantar keratoderma, follicular keratoses on the extensor surfaces of the knees and elbows, keratosis pilaris, blister formation on the feet and sometimes on the palms, callosities of the feet, leukokeratosis of the oral mucosa (often complicated by candidosis),^{772,773} hair abnormalities, and hyperhidrosis of the palms and soles. Acro-osteolysis is an uncommon

Figure 9.13 Acrokeratoelastoidosis. (A) There is hyperkeratosis with a shallow depression of the underlying epidermis. (H&E) (B) Elastic fibers are decreased in number, thin, and fragmented. (Verhoeff–van Gieson)

complication.⁷⁷⁴ These clinical features typify the so-called ‘type I’ (Jadassohn–Lewandowsky; OMIM 167200) cases.^{771,775} Patients with the type II variant (Jackson–Lawler type; OMIM 167210) have the addition of natal teeth (teeth erupted prior to birth) and multiple cutaneous cysts, either epidermal cysts or steatocystomas,^{776,777} but no oral leukokeratosis.⁷⁷⁸ Woolly hair was present in one case.⁷⁷⁹ In type III, the features of type I are accompanied by leukokeratosis of the cornea. Type IV combines the clinical features of the other types with laryngeal lesions, mental retardation, and alopecia.⁷⁸⁰

There is some variability in the age of onset of the various manifestations, but nail changes are usually present at birth or soon afterwards and become progressively more disfiguring during the first year of life. Nail dystrophy of late onset (pachyonychia congenita tarda) has been reported.^{781–784}

Pachyonychia congenita is usually inherited as an autosomal dominant trait with variable expression and high penetrance, although several cases with autosomal recessive inheritance have been reported.⁷⁸⁸

Type II pachyonychia congenita is due to an abnormality in the keratin 17 (*KRT17*) gene and in its expression partner keratin 6b (*KRT6B*),⁷⁸⁵ the former resulting from a gene mutation in the type I keratin cluster on chromosome 17q12–q21 and the latter from a mutation in *KRT6B* at 12q13.⁷⁸⁶ Similar mutations in the *KRT17* gene can cause steatocystoma multiplex with little or no nail dystrophy.⁷⁸⁷ *Type I pachyonychia congenita* results from a mutation in the helix initiation peptide of the keratin 16 (*KRT16*) gene^{788,789} or in the keratin 6a (*KRT6A*) gene located at 12q13.^{790–792} Mutations of *KRT6A* are said to be more frequent than those of *KRT16*⁷⁹³ and to be associated with more extensive disease.⁷⁹⁴ There are correlations between genotype and phenotype among *KRT16* mutations; for example, *p.Asn125Asp* and *p.Arg127Pro* mutations are associated with more severe disease than is the case for *p.Asn125Ser* and *p.Arg127Cys* mutations.⁷⁹⁵ Because of overlap in the clinical types, it has been proposed that a new genotype-based nomenclature be instituted.^{796,797}

The thickened nails and callosities have been treated with urea paste 40% with good results.⁷⁹⁸ As plantar sweating at high ambient temperatures increases the blistering of the plantar callosities, control of the sweating with injections of botulinum toxin has been carried out.⁷⁹⁹ This relieves the pain associated with walking on these callosities.⁷⁹⁹ Oral retinoids have been useful in some patients, although at times side effects appear to outweigh the benefits.⁸⁰⁰ Statins have been found to downregulate K6a promoter activity and may prove to be of therapeutic benefit.⁸⁰¹ Promising future therapies include the use of small interfering RNA (siRNA) or induced pluripotent stem cells (iPS).⁸⁰²

Mention is made here for completeness of **ectopic nails**. They have been reported on the volar surface of fingers and toes and elsewhere.⁸⁰³ Ectopic plantar nails are smaller than normal ones.⁸⁰⁴ Ectopic nails are most frequently caused by traumatic inoculation of nail matrix. They may be associated with polydactyly.⁸⁰⁵ Congenital malalignment of the great toenails is another malformation. It is heritable.⁸⁰⁶ The yellow nail syndrome (OMIM 153300) and other diseases of nails will not be considered further.^{807–813}

Histopathology

The involved mucous membranes and skin, including the nail bed, show marked intracellular edema involving cells in the upper malpighian layer and in the thickened stratum corneum.^{768,771,814–817} There is sometimes rupture of cell walls, particularly with lesions on plantar surfaces, with the formation of intraepidermal vesicles. The epidermis is markedly thickened as a consequence of the edema and the accompanying hyperkeratosis and focal parakeratosis.

The hyperkeratotic papules on the knees and elbows show hyperkeratosis, a prominent granular layer, and acanthosis.^{768,818} There is usually a thick horny plug extending above the infundibulum of the hair follicle. In one case, the plug resembled a cornoid lamella;⁸¹⁹ in another, the plug, which was not related to a follicle, penetrated into

the dermis in the manner seen in Kyrle’s disease (see p. 312).⁸²⁰ Horny plugs have also been described in sweat pores.⁸¹⁸

The plantar callosities show hyperkeratosis, focal parakeratosis, and sometimes mild papillomatosis and acanthosis. The granular layer is thick except for the area overlying any papillomatous foci.⁷⁷¹

Microscopic examination of plucked hairs from a patient with pachyonychia congenita and diffuse hair loss showed keratinization and cornification of the hair bulbs, without other specific hair shaft abnormalities.⁸²¹

Two kindreds have been reported with pigment incontinence and amyloid in the papillary dermis.⁸²²

CORNOID LAMELLATION

The cornoid lamella is a thin column of parakeratotic cells with an absent or decreased underlying granular zone and vacuolated or dyskeratotic cells in the spinous layer. It is the key histological feature of porokeratosis and its clinical variants, but like some of the other minor ‘tissue reaction patterns’ (see Chapter 1, p. 12) it can be found as an incidental phenomenon in a range of inflammatory, hyperplastic, and neoplastic conditions of the skin. The cornoid lamella represents a localized area of faulty keratinization and is manifest clinically as a raised keratotic or thin thread-like border to an annular, gyrate, or linear lesion.

Cornoid lamellation has been regarded as a clonal disease⁸²³ and as a morphological expression of disordered epithelial metabolism.⁸²⁴ Abnormal DNA ploidy and abnormalities of keratinocyte maturation have been demonstrated in the epidermis in some lesions of porokeratosis.^{825–828} Overexpression of p53 has been detected in the nuclei of keratinocytes in the basal layers of the epidermis beneath the cornoid lamella.^{829–832} This is accompanied by a reduction in mdm2 and p21.^{833,834} Gene expression profiling of porokeratosis has demonstrated similarities with psoriasis.⁸³⁵ Both are hyperproliferative disorders of keratinocytes.⁸³⁵ Both show increased connexin 30 expression.⁸³⁶

POROKERATOSIS AND VARIANTS

Porokeratosis is a genodermatosis with many different clinical expressions.⁸³⁷ Lesions may be solitary or numerous, inconspicuous or prominent, small or large (giant),^{838–842} atrophic or hyperkeratotic,⁸⁴³ and asymptomatic or pruritic.⁸⁴⁴ The lip,⁸⁴⁵ mouth,⁸⁴⁶ face,^{847–850} scalp,⁸⁵¹ nail fold,⁸⁵² penis,^{853,854} scrotum,⁸⁵⁵ genitocrural and perianal regions,^{856–860} and natal cleft⁸⁶¹ are sites that are rarely involved. Facial lesions may be destructive and disfiguring.^{862,863} Linear facial lesions have also been seen.⁸⁶⁴ Involvement of a burn scar has been reported.⁸⁶⁵ Other rare clinical associations include Crohn’s disease,⁸⁶⁶ trisomy 16,⁸⁶⁷ chronic renal failure,^{868,869} hepatitis C virus-related hepatocellular carcinoma,⁸⁷⁰ cholangiocarcinoma,⁸⁷¹ previous renal transplant,^{872–875} bone marrow transplantation,⁸⁷⁶ myelodysplastic syndrome,⁸⁷⁷ lymphedema,⁸⁷⁸ herpes simplex infection,⁸⁷⁹ systemic lupus erythematosus,⁸⁸⁰ microsatellite instability in association with hereditary nonpolyposis colorectal cancer,⁸⁸¹ lesions localized to the access region for hemodialysis,⁸⁸² and onset after electron beam radiation,^{883–885} PUVA,⁸⁸⁶ tanning salon use,⁸⁸⁷ prolonged topical corticosteroid use,⁸⁸⁸ and furosemide (frusemide).⁸⁸⁹ The simultaneous development of disseminated superficial actinic porokeratosis (DSAP) and ovarian cancer in one patient may have been coincidental rather than a true paraneoplastic association.⁸⁹⁰ Although it was originally regarded as a familial disease with autosomal dominant inheritance,⁸⁹¹ numerous nonfamilial cases have now been reported. Congenital cases are rare.^{864,892}

The most important clinical forms are *porokeratosis of Mibelli* (OMIM 175800), characterized by one or more round, oval, or gyrate plaques with an atrophic center and a thin, elevated, guttered,

keratotic rim that may show peripheral expansion, and *disseminated superficial actinic porokeratosis* (DSAP; OMIM 175900) consisting of multiple, annular, keratotic lesions less than 1 cm in diameter, with a hyperkeratotic, thread-like border and occurring particularly on the sun-exposed extremities.⁸⁹³⁻⁸⁹⁵ They usually develop during the third or fourth decade of life. DSAP appears to be heterogeneous with two forms identified – DSAP1 (OMIM 175900) tentatively linked to the 12q24.1 region, although nearby regions have also been suggested;^{896,897} and DSAP2 (OMIM 607728) on chromosome 15q25.1–26.1.⁸⁹⁸⁻⁹⁰⁰ Other candidate genes that have been suggested on chromosome 12 are slingshot 1 (*SSH1*) and *ARPC3*, both involved in the actin cytoskeleton pathway,^{900,901} and the *SART3* gene.⁹⁰² A locus has been discovered on 1p31.3–p31.1, for an autosomal dominant form of DSAP (DSAP3).⁹⁰³ Luan *et al.* recently identified a new locus on chromosome 16q24.1–24.3 (DSAP4).^{904,905}

Rare clinical variants include a linear⁹⁰⁶⁻⁹¹⁵ or systematized^{916,917} variant, a reticulate form,⁹¹⁸ a follicular variant,⁹¹⁹ an eruptive pruritic form,⁹²⁰ porokeratosis plantaris discreta^{921,922} (painful plantar lesions), porokeratotic palmoplantar keratoderma discreta,⁹²³ punctate porokeratotic keratoderma (also known as punctate porokeratosis),⁹²⁴⁻⁹²⁹ and porokeratosis punctata palmaris et plantaris – spiny keratoderma^{649,930,931} (PPPP; OMIM 175860 (asymptomatic pits or plugs, usually on the palms, digits, or soles and not universally accepted as a variant of porokeratosis)).⁹³² Other variants include linear palmoplantar porokeratotic hamartoma (the cornoid lamellae are not related to eccrine ostia),⁹³³ porokeratosis plantaris, palmaris et disseminata⁹³⁴⁻⁹⁴¹ (annular and serpiginous lesions on the palms and soles with later involvement of other areas (PPPD; OMIM 175850)), and the related superficial disseminated eruptive form.^{942,943} PPPD may be due to the same gene as DSAP1.⁸⁹⁸ Another rare variant of porokeratosis is a hyperkeratotic verrucous type.⁹⁴⁴⁻⁹⁴⁶ In yet another variant, craniosynostosis, anal anomalies, and porokeratosis are associated (CAP syndrome; OMIM 603116).⁹⁰² Closely related are the cases with cornoid lamellae in eccrine and hair follicle ostia, described as ‘porokeratotic eccrine ostial and dermal duct nevus’,⁹⁴⁷⁻⁹⁵⁸ ‘porokeratotic eccrine duct and hair follicle nevus’,^{959,960} and ‘reticular erythema with ostial porokeratosis’.⁹⁶¹ Porokeratotic eccrine ostial and dermal duct nevus is most commonly found on the palms and soles. It usually presents in early childhood with a linear distribution of asymptomatic papules.⁹⁵⁸ The lesions may develop along Blaschko’s lines^{962,963} or be systematized.⁹⁶⁴ Ptychotropic porokeratosis, so named because of its preference for body folds (ptych-, from the Greek *ptyssein*, meaning to fold), consists of pruritic reddish-brown papules in plaques on the buttocks and genital region.⁹⁶⁵

Porokeratoma is a recently described solitary, hyperkeratotic plaque or nodule, sometimes verrucous, with a predilection for the distal extremities of middle-aged to elderly males.⁹⁶⁶ It is akin to warty dyskeratoma and epidermolytic acanthoma.

The disseminated superficial actinic variant coexists rarely with other types of porokeratosis, particularly the linear type.^{908,912,967-971} The association of these two forms is an example of type 2 segmental involvement, occurring in an autosomal dominant skin disorder.⁹⁷² Coexistence of DSAP, linear porokeratosis, and verrucous porokeratosis has recently been reported.⁹⁷³ The coexistence of DSAP and porokeratosis of Mibelli has also been reported.⁹⁷⁴ The various clinical types of porokeratosis are listed in **Table 9.4**.

DSAP may be exacerbated by exposure to ultraviolet light,^{975,976} but it does not appear to be due to radiation hypersensitivity.⁹⁷⁷ There appears to be an inherent defect in the terminal differentiation program.^{977,978} Both DSAP and porokeratosis of Mibelli have developed in immunosuppressed patients.⁹⁷⁹⁻⁹⁸⁶ Age-related immunosuppression has been used to explain the occurrence of disseminated porokeratosis in the elderly.⁹⁸⁷

Reflectance confocal microscopy has been used to diagnose DSAP and to distinguish lesions from actinic keratoses. The cornoid lamella

Table 9.4 Variants of porokeratosis

Porokeratosis of Mibelli (including site-specific variants of face, scalp, and anogenital region)
Linear and systematized porokeratosis
Hyperkeratotic verrucous porokeratosis
Disseminated superficial actinic porokeratosis (types 1, 2, and 3)
Disseminated eruptive porokeratosis
Follicular porokeratosis
Inflammatory porokeratosis
Eruptive pruritic porokeratosis
Palmoplantar porokeratoses
Porokeratosis plantaris discreta
Porokeratotic palmoplantar keratoderma discreta
Punctate porokeratotic keratoderma (punctate porokeratosis)
Porokeratosis punctata palmaris et plantaris (spiny keratoderma)
Linear palmoplantar porokeratosis
Porokeratosis plantaris, palmaris et disseminata
Porokeratotic eccrine ostial and dermal duct nevus
Porokeratotic eccrine duct and hair follicle nevus
Porokeratoma
CAP syndrome (craniosynostosis, anal anomalies and porokeratosis)
Porokeratosis ptychotropica

is easily identified by this technique.⁹⁸⁸ Other dermoscopic methods can also be used.^{989,990} Fake sun tan lotion will highlight lesions of DSAP serendipitously.⁹⁹¹ Povidone–iodine can also be used to highlight the cornoid lamella.⁹⁹²

Porokeratotic lesions are usually persistent, although clearance with subsequent recurrence has been reported.⁹⁹³ The development of squamous cell carcinoma^{831,971,994-998} or intraepidermal carcinoma^{999,1000} is a rare clinical complication of several of the variants of porokeratosis. The linear type is particularly prone to malignant change.¹⁰⁰¹⁻¹⁰⁰³ Fatal squamous cell carcinomas have developed in transplant-associated porokeratosis.¹⁰⁰⁴ The term ‘malignant disseminated porokeratosis’ has been applied to several cases in which the porokeratotic lesions had a significant potential to undergo malignant degeneration.^{1005,1006} Allelic loss has been suggested as a possible pathogenetic mechanism for these tumors.¹⁰⁰¹

Treatment of porokeratosis is notoriously difficult. Shave excision, cryosurgery, electrocautery, carbon dioxide laser, topical 5-fluorouracil, keratolytics, and topical retinoids have been used.¹⁰⁰⁷ Successful treatment with 5% imiquimod cream has also been reported.¹⁰⁰⁷ Fractional photothermolysis using an erbium-doped laser has also been effective.¹⁰⁰⁸ Vitamin D analogues have been used successfully in a number of reports,^{1009,1010} although in one split-face trial, high-dose tacalcitol was not as effective as CO₂ laser-induced ring abrasion in producing clearing of lesions.¹⁰¹¹

Histopathology

It is important that the biopsy is taken across the edge of the peripheral rim in order to show the typical cornoid lamella, the features of which have been described previously. Multiple cornoid lamellae will usually be seen in biopsies from the linear and reticulate form. There may be two cornoid lamellae, one on each side of a keratotic plug, at either edge of a lesion of DSAP (**Fig. 9.14**).¹⁰¹² In porokeratosis of Mibelli, there is invagination of the epidermis at the site of the cornoid lamella with adjacent mild papillomatosis. A PAS stain reveals that the cornoid lamella contains numerous purple granules,

Figure 9.14 Porokeratosis. There are two cornoid lamellae close together. One overlies an acrosyringium. Follicular infundibula may also be involved. (H&E)

representing intracellular glycogen and glycoproteins.¹⁰¹³ Beneath the lamella, there is absence or diminution of the granular layer, sometimes only several cells in width (**Fig. 9.15**). However, in the solitary palmar or plantar lesions, the cornoid lamella is quite broad with a corresponding wide zone where the underlying granular zone is absent or markedly reduced. Sometimes one or more dyskeratotic cells are present in the spinous layer. Basal vacuolar change and vacuolated cells in the spinous layer are other changes found beneath the cornoid lamella.¹⁰¹⁴

The case reported as multiple minute parakeratotic keratoses of the hand in a patient with systemic lupus erythematosus appears to be a variant of punctate porokeratotic keratoderma.¹⁰¹⁵

Beneath the lamella, there are often dilated capillaries in the papillary dermis, associated with a lymphocytic infiltrate. A variant with numerous eosinophils resembling somewhat a bite reaction is exceedingly rare. The most prominent inflammatory changes are seen in DSAP, in which a superficial band-like infiltrate with lichenoid (interface) qualities is usually present. One should never sign out a case as lichen planus-like keratosis (benign lichenoid keratosis) until the presence of cornoid lamellae has been confidently excluded. The infiltrate is usually present inside the porokeratotic rim.¹⁰¹⁴ In addition, the epidermis between the lamellae is often atrophic in this form, with overlying hyperkeratosis, and the dermis may show solar elastotic changes. Focal epidermal necrosis and ulceration have been reported at the periphery of a lesion of porokeratosis.^{1016,1017} Subepidermal blistering is a rare event.¹⁰¹⁸ Amyloid has been found in the papillary dermis in several cases.^{1019–1023} Histological examination of porokeratoma shows a well-defined lesion, characterized by acanthosis and verrucous hyperplasia with prominent multiple and confluent cornoid lamellae.⁹⁶⁶ In another recent case, there was low papillomatosis, and cornoid lamellae were rather broad-based.¹⁰²⁴

Electron microscopy

Scanning electron microscopy has shown bud-like spreading of the active edge,¹⁰²⁵ whereas transmission electron microscopy has demonstrated that the basophilic granular material in the cornoid lamella consists of degenerate cells with pyknotic nuclei.¹⁰²⁶ Langerhans cells are in close contact with degenerating keratinocytes.¹⁰²⁷ The granular layer is inconspicuous, with only small amounts of keratohyalin. Vacuolated cells and others showing filamentous degeneration ('dyskeratotic' cells) are often present. Apoptotic bodies may be seen in the basal layer and in the dermal papillae.¹⁰²⁸

Figure 9.15 Porokeratosis. The parakeratotic column (cornoid lamella) overlies an area several cells in width, in which the granular layer is absent. (H&E)

Differential diagnosis

Although the cornoid lamella is characteristic of porokeratosis, similar structures can be observed, for example, in actinic keratosis and verrucae. In these circumstances, finding significant basilar keratinocyte atypia not confined to the parakeratotic column (in actinic keratosis) or viral inclusions (in verrucae) is diagnostically important. The porokeratotic eccrine ostial and dermal duct nevus and porokeratotic eccrine duct and hair follicle nevus are closely related entities in which the parakeratotic columns are associated with dilated eccrine ducts or follicular units.

EPIDERMOLYTIC HYPERKERATOSIS

Epidermolytic hyperkeratosis is an abnormality of epidermal maturation characterized by compact hyperkeratosis, accompanied by granular and vacuolar degeneration of the cells of the spinous and granular layers (**Fig. 9.16**). It may be a congenital or an acquired defect. This histological pattern may be seen in a number of different clinical settings, some of which are considered in other sections of this chapter. It may be the following:

Figure 9.16 Epidermolytic hyperkeratosis. Compact orthokeratosis overlies an epidermis showing granular and vacuolar change in its upper layers. (H&E)

Figure 9.17 Linear nevus of epidermolytic hyperkeratotic type. (H&E)

- *Generalized*: bullous ichthyosis (see p. 287)
- *Systematized or linear*: epidermal nevus variant (see below and p. 785)
- *Palmoplantar*: palmoplantar keratoderma variant (see p. 294)
- *Solitary*: epidermolytic acanthoma (see below)
- *Multiple discrete*: disseminated epidermolytic acanthoma (see below)
- *Incidental*: focal epidermolytic hyperkeratosis (see below)
- *Solar keratosis related*: a rare variant of solar keratosis (see p. 798)
- *Follicular*: nevoid follicular epidermolytic hyperkeratosis (see below)
- *Mucosal*: epidermolytic leukoplakia.

Epidermolytic hyperkeratosis is a relatively uncommon histological pattern in epidermal nevi, being present in only 8 of 160 cases reported from the Mayo Clinic (the clinical appearance of the lesions in this series is not described).¹⁰²⁹ There are reports of cases with a systematized pattern (ichthyosis hystrix)^{1030,1031} and with a linear pattern (Fig. 9.17).^{1031,1032} Bullous ichthyosis (generalized epidermolytic hyperkeratosis) has been reported in the offspring of patients with the linear form

of the disease.^{1031,1033} This is an example of the reverse of type 2 segmental involvement occurring in an autosomal dominant skin condition. It is unusual for those with segmental disease to pass on the generalized form.

Focal epidermolytic hyperkeratosis has been found incidentally in a range of circumstances, including the wall of an infundibular cyst,¹⁰³⁴ in a seborrheic keratosis, in a cutaneous horn and a skin tag, overlying an intradermal nevus, and even in association with dermatoses.²¹⁴ Its incidence appears to be increased adjacent to dysplastic nevi.^{1035,1036} Epidermolytic hyperkeratosis has also been found rarely in solar keratoses¹⁰³⁷ and in leukoplakic lesions of the lips^{1037,1038} and prepuce.¹⁰³⁹ It may involve the oral mucosa.¹⁰⁴⁰ It has been observed on the labia and mons pubis, where it produced seven verrucoid papules resembling condylomas.¹⁰⁴¹ It may be found adjacent to any lesion as an incidental phenomenon.^{1042,1043}

The nevoid follicular variant¹⁰⁴⁴ presents as comedo-like follicular papules that may have the appearance of nevus comedonicus.^{1045,1046} A linear nevus comedonicus has been reported with the histological pattern of epidermolytic hyperkeratosis.¹⁰⁴⁷ It may also involve the intraepidermal eccrine sweat duct.^{1048,1049}

If there is continuous involvement of the entire horizontal epidermis, then the patient is likely to have generalized epidermolytic hyperkeratosis (bullous congenital ichthyosiform erythroderma). The presence of focal epidermolytic hyperkeratosis with skip areas of normal-appearing epidermis correlates usually with mosaic disease.¹⁰⁵⁰

Electron microscopy

There are similar ultrastructural changes in the different variants of epidermolytic hyperkeratosis.¹⁰⁵¹ There is clumping of tonofilaments and cytoplasmic vacuolation. Keratohyaline granules are of variable size.

EPIDERMOLYTIC ACANTHOMA

Epidermolytic acanthoma is an uncommon lesion that presents clinically as a wart in patients of all ages.^{1052,1053} A disseminated form has also been reported;^{1054–1057} in one report of four cases, the lesions developed after sun exposure.¹⁰⁵⁸ Solitary epidermolytic acanthomas occur most commonly on genital skin.¹⁰⁵⁹ Trauma has also been incriminated.¹⁰⁵⁷ Multiple scrotal epidermolytic acanthomas have been reported. They were thought to have resulted from the trauma of chronic scratching.¹⁰⁶⁰

Histopathology

The lesions show the typical features of epidermolytic hyperkeratosis. The entire thickness of the epidermis may be involved or only the upper part of the nucleated epidermis (Fig. 9.18). Three epidermal configurations have been described: papillomatous, cup-shaped, and acanthotic.¹⁰⁶¹ Polypoid lesions are uncommonly observed.¹⁰⁵⁹ Other findings observed with varying frequency include follicular involvement, focal acantholysis, necrotic cells or mitotic figures, prominent upper dermal vessels, and perivascular lymphocytic infiltrates.¹⁰⁵⁹ There is a diminution in the expression of K1 and K10 in the altered granular layer of lesional skin.¹⁰⁵³

ACANTHOLYTIC DYSKERATOSIS

Acantholytic dyskeratosis is a histological reaction pattern characterized by suprabasilar clefting with acantholytic and dyskeratotic cells at all levels of the epidermis (Fig. 9.19).¹⁰⁶² It may also be regarded as a special subdivision of the vesiculobullous tissue reaction, but it is considered in this chapter because the vesiculation is not usually apparent clinically and the primary abnormality involves the tonofilament-desmosome complex with disordered epidermal maturation.

Figure 9.18 Epidermolytic acanthoma. (A) Clinically, this was a solitary, keratotic lesion. (B) Another case with a flatter epidermis and more overlying keratin. (H&E)

Figure 9.19 (A) Acantholytic dyskeratosis. (B) There is suprabasal clefting with occasional acantholytic and dyskeratotic cells. (H&E)

Like epidermolytic hyperkeratosis, acantholytic dyskeratosis may be found in a number of different clinical settings.¹⁰⁶² The two histological patterns have even been found in the same biopsy.¹⁰⁶³ Acantholytic dyskeratosis may be as follows:

- *Generalized*: Darier's disease (see p. 304)
- *Systematized or linear*: zosteriform (segmental) Darier's disease or linear nevus (see below and p. 785)
- *Transient*: Grover's disease (see p. 306)
- *Palmoplantar*: a very rare form of keratoderma (see p. 296)
- *Solitary*: warty dyskeratoma (see p. 310)
- *Incidental*: focal acantholytic dyskeratosis (see below)
- *Solar keratosis related*: acantholytic solar keratosis (see p. 154)
- *Mucosal*: vulval and anal acantholytic dyskeratosis (see below).

Of the various clinical settings listed above, focal acantholytic dyskeratosis, Darier's disease, Grover's disease, and warty dyskeratoma are considered separately. Hailey-Hailey disease (familial benign chronic pemphigus) is also included in this section because of some overlap features with Darier's disease. However, in Hailey-Hailey

disease, the acantholysis is more extensive and dyskeratosis is not a prominent feature. Only brief mention is made of the other clinical settings because of their rarity or because they belong more appropriately to another section of this volume.

The occurrence of acantholytic dyskeratosis in lesions with a linear or systematized distribution is best regarded as an example of segmental Darier's disease induced by postzygotic mosaicism¹⁰⁶⁴⁻¹⁰⁷⁰ and not as an example of epidermal nevus as previously thought.¹⁰⁷¹⁻¹⁰⁷⁴ It is now well-known that autosomal dominant skin disorders may sometimes become manifest in a mosaic form, involving the body in a linear, patchy, or circumscribed arrangement.¹⁰⁷⁵⁻¹⁰⁷⁷ The segmental disease usually shows the same degree of severity as that found in the corresponding nonmosaic trait.¹⁰⁷⁵ Loss of heterozygosity for the same allele causes more severe changes.^{1075,1078} Segmental Darier's disease shows the same mutations in the *ATP2A2* gene that occur in generalized Darier's disease. Unaffected skin does not show this mutation, in keeping with mosaicism.¹⁰⁷⁹ Acantholytic dyskeratosis is an uncommon finding in 'epidermal nevi', being present in only 2 of a series of 167 epidermal nevi reported from the Mayo Clinic.¹⁰²⁹ Such lesions would have followed Blaschko's lines, reflecting as it

does genetic mosaicism.¹⁰⁸⁰ The sole of the foot is a rare site for segmental disease.¹⁰⁸¹

Acantholytic dyskeratosis has also been reported as a rare pattern in familial dyskeratotic comedones, a condition with some features in common with nevus comedonicus (see p. 787).¹⁰⁸²

Acantholytic dyskeratosis appears to affect cells within the germinative cellular pool of the epidermis.¹⁰⁸³ The dyskeratosis that occurs within the acantholytic cells is probably a secondary phenomenon because the acantholytic cells are metabolically inert.¹⁰⁸³

FOCAL ACANTHOLYTIC DYSKERATOSIS

Although the term ‘focal acantholytic dyskeratosis’ is often used both for clinically inapparent incidental foci and for clinically apparent solitary lesions with the histological pattern of acantholytic dyskeratosis,¹⁰⁸⁴ some authors restrict its use to its incidental finding in histological sections. This is not an uncommon event.^{1085,1086} Ko and colleagues coined the term ‘acantholytic dyskeratotic acanthoma’ for this lesion, apparently on the basis that it is more than an incidental finding, and it often presents clinically as a basal cell carcinoma of the trunk.¹⁰⁸⁷ The author sees at least one case each week of this phenomenon, whether it be incidental or otherwise. The term ‘papular acantholytic dyskeratoma’ has been applied to the clinically apparent solitary lesions,¹⁰⁸⁸ and the term ‘papular acantholytic dyskeratosis’ has been applied to the exceedingly rare cases in which multiple lesions have developed on the vulva,^{1089–1095} perianal area,^{1096–1098} or penis¹⁰⁹⁹ (discussed later). A clinically apparent lesion has also been reported on the lip.¹⁰⁸⁴ A case reported as ‘congenital acantholytic dyskeratotic dermatosis’ appears to be a variant of papular acantholytic dyskeratosis. There were multiple erosive papules and plaques located on the left thigh, left ankle, and right neck that were present at birth.¹¹⁰⁰ There was no family history of Darier’s disease, and no genetic studies were performed.¹¹⁰⁰

Incidental focal acantholytic dyskeratosis is statistically increased in atypical melanocytic lesions.¹¹⁰¹

Histopathology

There is acantholytic dyskeratosis, as already defined (discussed previously). Hyperkeratosis is less prominent in incidental lesions than in Darier’s disease. Warty dyskeratomas differ from focal acantholytic dyskeratomas by having more prominent villi, clefting, and corps ronds. Some of the genital and crural cases, mentioned previously, have a histological resemblance to Hailey–Hailey disease, with marked acantholysis and little dyskeratosis. They belong to the recently recognized acantholytic subset of acantholytic dyskeratosis; another subset features dyskeratosis alone (see later).

In one case of papular acantholytic dyskeratosis of the anogenital region, immunofluorescence showed intercellular IgG and C3 within the epidermis.¹¹⁰²

Acantholytic subset

Acantholysis, with little or no dyskeratosis, can be seen as an incidental phenomenon¹¹⁰³ or as a solitary tumor of the skin – acantholytic acanthoma (see p. 790).^{1104,1105} This pattern has also been found in multiple papules¹¹⁰⁶ and as a variant of epidermal nevus with horn-like processes. This latter case was reported as ‘nevus corniculatus’.¹¹⁰⁷

A high proportion of the rare genital, crural, and perineal cases referred to as papular acantholytic dyskeratosis (discussed previously) have had a histological resemblance to Hailey–Hailey disease, with prominent acantholysis and little or no dyskeratosis.^{1091,1108–1110} Other cases have resembled acantholytic dyskeratosis.¹⁰⁹⁵ An appropriate designation for these cases would seem to be ‘acantholytic dermatosis

of the genitocrural/perineal region’.¹¹¹¹ The exact classification of the vulval case with histological resemblance to pemphigus vegetans remains to be determined.¹¹¹² Another case of this entity was reported as warty dyskeratoma.^{1113,1114} Incidentally, it responded to tazarotenic acid.¹¹¹³

Generalized acantholysis is seen in Hailey–Hailey disease. It is discussed on page 308. A peculiar form of acantholysis, localized to the acrosyringium, has been reported in several febrile patients. The clinical picture resembled Grover’s disease.¹¹¹⁵ The authors proposed the name ‘*sudoriferous acrosyringial acantholytic disease*’.¹¹¹⁵

Finally, acantholysis with minimal dyskeratosis can be seen, as an incidental phenomenon, in other disease processes, such as pityriasis rubra pilaris¹¹¹⁶ and seborrheic keratoses.

Dyskeratotic subset

Although regarded as a variant of epidermolytic acanthoma, the isolated lesion reported as ‘*isolated dyskeratotic acanthoma*’ is best classified here.¹¹¹⁷ It combined dyskeratotic cells throughout the epidermis with a parakeratotic horn containing large rounded cells at all levels.¹¹¹⁷

The term ‘*acquired dyskeratotic acanthosis*’ has been applied to a case in which multiple maculopapules, 3–8 mm in diameter, developed in sun-exposed areas. There were clusters of parakeratotic cells that appeared eosinophilic to ‘ghost-like’. The epidermis was papillomatous and acanthotic with foci of dyskeratotic keratinocytes.¹¹¹⁸

The proliferation of terms for solitary cases showing acantholysis, dyskeratosis, or both, and in variable proportions, is bordering on the ridiculous. Perhaps prospective authors should attempt consolidation rather than further ‘splitting’.

DARIER’S DISEASE

Darier’s disease (OMIM 124200) is a rare, autosomal dominant genodermatosis in which greasy, yellow to brown, crusted papular lesions develop, mainly in the seborrheic areas of the head, neck, and trunk.^{1119–}

¹¹²² A rare acral variant exists;^{1123,1124} lesions are sometimes hemorrhagic in this form.¹¹²⁵ The coalescence of papules produces plaques, which may at times become papillomatous. The prevalence of Darier’s disease varies from 1:30,000 in areas of Scotland to 1:100,000 in Denmark.^{1126,1127} It is much less common in Singapore.¹¹²⁸ Onset is usually in early adolescence, and the disease runs a chronic course. Congenital onset is rare.¹¹²⁹ There is an equal sex incidence, but its clinical expression is usually milder in females.¹¹²⁷ Verrucous lesions resembling acrokeratosis verruciformis may be present on the dorsum of the hands and feet in approximately 70% of cases.^{1121,1130}

Punctate keratoses are sometimes found on the palms and soles.¹¹³⁰ Longitudinal striations are usually present in the nails.¹¹³¹ Rare clinical variants include a bullous,^{1132,1133} a comedonal,^{1134–1137} and a hypertrophic (cornifying) form.^{1138,1139} Comedomal Darier’s has clinical features similar to acne and histopathological features akin to warty dyskeratoma. It is exceedingly rare.¹¹⁴⁰ A ‘groversid’ variant with smooth papules has been reported. It was of late onset.¹¹⁴¹ Cutaneous depigmentation (guttate leukoderma),^{1142–1146} secondary eczematization,¹¹⁴⁷ cutis verticis gyrata,¹¹⁴⁸ mucosal lesions,^{1149,1150} ocular disorders,¹¹⁵¹ bone cysts,¹¹⁵² gynecomastia,¹¹⁵³ and mental deficiency¹¹⁵⁴ have also been recorded. Mucosal lesions usually involve the mouth, but the esophagus has also been involved.¹¹⁵⁵ Darier’s disease has been exacerbated and/or initiated by lithium carbonate therapy,¹¹⁵⁶ azathioprine treatment for thyroid-related eye disease,¹¹⁵⁷ and UVB radiation.^{1128,1158,1159}

A variant restricted to sun-exposed areas has been reported.¹¹⁶⁰ A paraneoplastic variant has also been reported.¹¹⁶¹ An association with seronegative spondyloarthritis, associated with HLA-B27 positivity, has been reported on several occasions.¹¹⁶² Localized (segmental) disease has been precipitated by the administration of menotropin,¹¹⁶³

and it has been associated with Gardner's syndrome in one case.¹¹⁶⁴ Patients with segmental, unilateral, or localized lesions are regarded as examples of mosaicism. They were discussed in the introduction to this section (see p. 304). The involved skin has the same genetic mutation that occurs in the generalized form of Darier's disease.¹⁰⁷⁹ In one case, unilateral Darier's disease involving the entire right side of the body was present. It was associated with unilateral guttate leukoderma. Lesions did not follow Blaschko's lines as is usual in localized and segmental disease.¹¹⁶⁵ The case reported as unilateral Grover's disease along Blaschko's lines was probably linear Darier's disease.^{1166,1167}

There is a predisposition to bacterial, fungal, and viral infections, although no consistent and specific immunological abnormality has been demonstrated.^{1119,1128,1168,1169} There is a high prevalence of *Staphylococcus aureus* colonization in nares and lesional skin, with a correlation between the extent of colonization and disease activity.¹¹⁷⁰ Infection with herpes simplex virus, vaccinia,¹¹⁷¹ and even coxsackievirus A16¹¹⁷² may produce the features of Kaposi's varicelliform eruption^{1173–1176} (see Chapter 26, p. 726). Herpes zoster has occurred in linear Darier's disease in a patient infected with HIV.¹¹⁷⁷ An HPV-related subungual squamous cell carcinoma has been reported.¹¹⁷⁸

The mechanism of acantholysis in Darier's disease is still the subject of controversy.¹¹¹⁹ It is usually ascribed to a defect in the synthesis, organization, or maturation of the tonofilament–desmosome complexes.¹¹⁷⁹ Ca^{2+} -ATPases play a key role in the assembly of desmosomes.¹¹⁸⁰ It appears that the proteins of the desmosomal attachment plaque are primarily affected.^{1181,1182} There is a loss of desmoplakin I and II and plakoglobin from the desmosomes.¹¹⁸¹ This results from an abnormality in the sorting of desmoplakin.¹¹⁸⁰ The pathogenetic significance of the finding that there is a delay in the expression of the suprabasal skin-specific keratins is uncertain.¹¹⁸³ Loss of desmosomal adhesion triggers anoikis,¹¹⁸⁴ a type of apoptosis characterized by cell detachment. This process contributes to the formation of dyskeratotic cells.¹¹⁸⁰ The loss of Bcl-2 and Bcl-x in lesional skin of Darier's disease reflects an imbalance in the apoptotic pathway in this disease.^{1185,1186} The adherens junction is another site of abnormality.¹¹⁸⁷

The genetic defect in Darier's disease has been mapped to chromosome 12q23–q24.1.^{1188–1191} It is due to mutations in the *ATP2A2* gene, which encodes the sarco/endoplasmic reticulum Ca^{2+} -ATPase type 2 isoform (SERCA2), a keratinocyte Ca^{2+} pump.^{1192,1193} Several isoforms of SERCA exist: SERCA2a, SERCA2b, and SERCA3.¹¹⁹⁴ Their differential expression may explain the localization of lesions. Variable clinical severity may occur in different members of the same family,¹¹⁹⁵ but no involvement of other organs in which SERCA2 plays a role has been found.¹¹⁹⁶ No particular mutational 'hot spots' have been found to explain the phenotypic variation that occurs in some pedigrees with Darier's disease.¹¹⁹³ Numerous mutations have now been described in this gene.^{1197–1199} In one novel missense mutation, the disease was restricted to the extremities.¹²⁰⁰

Despite significant side effects, oral retinoids are the most effective treatment for generalized or severe Darier's disease.¹²⁰¹ The response to topical retinoids is often poor.¹¹²⁸ Topical 5-fluorouracil is a promising treatment option, although its use has been limited,¹²⁰² and recent studies suggest that initial response to this therapy is followed by loss of efficacy over time.¹²⁰³ Topical tacrolimus gave encouraging results in one patient forced to cease isotretinoin due to major depression.¹²⁰¹ Potassium permanganate compresses and topical corticosteroids have been used for inflamed and macerated lesions.¹¹²⁸ Other therapies have included tacalcitol lotion with sunscreen,¹²⁰⁴ photodynamic therapy,¹²⁰⁵ electron beam therapy,¹²⁰⁶ adapaline gel,¹²⁰⁷ and topical pimecrolimus.¹²⁰⁸

Histopathology

An individual papule of Darier's disease shows suprabasal acantholysis with the formation of a small cleft (lacuna). Irregular projections of the papillary dermis covered by a single layer of basal cells, the so-called 'villi', extend into the lacunae (Fig. 9.20).¹¹¹⁹ A thick orthokeratotic plug,

Figure 9.20 Darier's disease. There is suprabasal clefting with a thickened stratum corneum and some dyskeratotic cells in the epidermis. (H&E)

often showing focal parakeratosis, overlies each lesion. Mild papillomatosis is often present.

Two characteristic types of dyskeratotic cell are present – *corps ronds* and *grains*. The *corps ronds* are found as solitary cells or sometimes small groups of separated cells in the upper malpighian layer and stratum corneum.¹²⁰⁹ They have a small pyknotic nucleus, a clear perinuclear halo, and brightly eosinophilic cytoplasm. The *grains* are small cells with elongated nuclei and scant cytoplasm in the upper layers of the epidermis. They resemble parakeratotic cells but are somewhat larger (Fig. 9.21).

As a general rule, the keratin plug is much thicker in lesions of Darier's disease than it is in Grover's disease. Furthermore, a few eosinophils are almost invariable in the upper dermis in Grover's disease. They are less common in uncomplicated Darier's disease.

The keratotic papules on the dorsum of the hands resemble those seen in acrokeratosis verruciformis, but small foci of suprabasal acantholytic dyskeratosis may be seen if serial sections are examined.

The cases reported as comedonal Darier's disease have had multiple lesions resembling warty dyskeratoma (Fig. 9.22).^{1134,1135} These feature dilated follicular infundibula containing parakeratotic material and also typical changes of clefting, lacunae, villi, and corps ronds and grains in the underlying and adjacent follicular infundibula.¹¹³⁷ Bullous lesions can have a configuration resembling exaggerated suprabasilar clefting of typical Darier's disease but in other cases may show a 'dilapidated brick wall' acantholysis with lesser degrees of dyskeratosis, more closely resembling the blisters of Hailey–Hailey disease (see later).¹²¹⁰

Immunoglobulins and C3 have been found in the intercellular areas of affected skin by direct immunofluorescence;¹²¹¹ this finding has not been confirmed in other studies.¹²¹² There is premature expression of involucrin in the lower epidermal layers.¹²¹³ There is strong labeling for involucrin in both keratinocyte cell membrane and cytoplasm.¹²¹³

Confocal reflectance microscopy has been used to make the diagnosis.¹²¹⁴

Electron microscopy

The *corps ronds* have a vacuolated perinuclear halo surrounded by a ring of tonofilaments aggregated with keratohyaline granules.^{1215–1217} The *grains* show premature aggregation of tonofilaments.¹²¹⁷ The synthesis of keratohyalin in association with clumped tonofilaments is peculiar to Darier's disease.¹²¹⁷ It is not seen in Hailey–Hailey disease. As previously mentioned, there is controversy regarding whether the withdrawal of the tonofilaments from the attachment plate of the desmosomes is the primary event in the acantholytic process or merely

Figure 9.21 Darier's disease. Dyskeratotic cells (corps ronds) are present above the suprabasal cleft. (H&E)

secondary to the splitting of the desmosomes.¹²¹⁸ Another ultrastructural finding in Darier's disease is the presence of cytoplasmic processes projecting from the basal keratinocytes into the underlying dermis through small defects in the basal lamina.¹²¹⁹

Differential diagnosis

In addition to Grover's disease, warty dyskeratoma, and some examples of acrokeratosis verruciformis (see later), the microscopic findings of Darier's disease can be seen in acantholytic, dyskeratotic acanthoma (and variants), and as an incidental finding in biopsy specimens obtained for other reasons. Each of these disorders has a distinctive clinical presentation (except for incidental acantholytic dyskeratosis) and microscopically is composed of smaller or more discrete lesions. Grover's disease lesions also display a histopathologic variability not generally seen in Darier's disease.

GALLI-GALLI DISEASE

Galli-Galli disease is an acantholytic variant of Dowling-Degos disease, an autosomal dominant disorder characterized by progressive pigmented lesions involving large body folds and flexural areas.¹²²⁰ It is

Figure 9.22 (A) Comedonal Darier's disease. (B) There are basal layer downgrowths with villi, resembling those seen in warty dyskeratoma. (H&E)

due to a mutation of the keratin 5 (*KRT5*) gene on chromosome 12q13. Mutations in this gene are also responsible for epidermolysis bullosa simplex with palmoplantar keratoderma.¹²²¹ The term 'Galli-Galli' is derived from the family name of the two brothers originally reported with this variant.¹²²⁰

Histopathology

There are multiple foci of acantholysis within the suprabasal and upper spinous layers with overlying parakeratosis. Dyskeratotic cells have been described in some cases but are generally not observed.¹²²²⁻¹²²⁴ Elongated, finger-like strands of keratinocytes extend into the papillary dermis.¹²²⁰

GROVER'S DISEASE

The eponymous designation Grover's disease is the preferred title for several closely related dermatoses characterized by the sudden onset of small, discrete, sometimes crusted, erythematous papules and papulovesicles.¹²²⁵⁻¹²²⁷ They usually develop on the upper trunk of older men. A zosteriform variant has been reported,¹²²⁸ as have bilateral lesions following Blaschko's lines.¹²²⁹ Lesions may be transient, lasting for weeks or several months¹²²⁵ (transient acantholytic dermatosis), or they may persist for several years¹²³⁰ (persistent acantholytic

dermatosis^{1231–1233} or papular acantholytic dermatosis¹²³⁴). Intense pruritus is often present. Oral involvement has been reported,¹²³⁵ as has the coexistence of other dermatoses such as asteatotic eczema,^{1236,1237} allergic contact dermatitis,¹²³⁷ atopic eczema,^{1237,1238} psoriasis,¹²³⁶ pemphigus foliaceus,¹²³⁹ a drug reaction, and a neutrophilic dermatosis in association with Waldenström's macroglobulinemia.¹²⁴⁰

Some cases of Grover's disease have followed or been exacerbated by exposure to ultraviolet light.^{1232,1234} Cases associated with lentiginous sun-induced 'freckling' have been reported.^{1241,1242} A few are associated with chronic renal failure.^{1243,1244} One case involved a febrile postoperative patient.¹²⁴⁵ The role of heat, persistent fever, and sweating has been postulated in the etiology of this condition.^{1246–1249} This theory has been challenged as a consequence of the study performed at the Ackerman Academy of Dermatopathology in New York.¹²⁵⁰ Grover's disease was present in 0.09% of biopsy specimens. It was diagnosed approximately four times more commonly in winter than in summer. It was suggested that Grover's disease arises against a backdrop of a xerotic epidermis with decreased sweat production rather than being caused by sweating and heat as previously postulated.¹²⁵⁰ Both mechanisms are probably involved. The cytokine IL-4, the synthetic guanosine analogue ribavirin,¹²⁵¹ and D-penicillamine therapy¹²⁵² have all precipitated Grover's disease.¹²⁵³ Other chemotherapeutic agents, often used in 'cocktail' form, have also resulted in Grover's disease,¹²⁵⁴ including anastrozole.¹²⁵⁵ Other drugs appear to precipitate this condition, and the author is currently supervising a study of more than 300 cases of Grover's disease to elucidate its clinical associations. In cases thought to have been drug-related, cessation of the drug has not necessarily led to the cure of the Grover's disease.

Several mechanisms are theoretically possible as explanations for the occurrence of Grover's disease in cancer patients.^{1256–1258} Several cases appear to have followed induction therapy, and one followed the use of 2-chlorodeoxyadenosine in the treatment of hairy cell leukemia.¹²⁵⁹ Other cases have been in patients who underwent high-dose chemotherapy followed by bone marrow transplantation or autologous stem cell infusion.¹²⁶⁰ Paslin suggested impairment of keratinocyte cholinergic receptors as a possible cause of Grover's disease; this is based on a patient whose Grover's disease flared while curtailing his smoking through the use of the nicotine receptor partial agonist varenicline.¹²⁶¹

Despite the histological similarity to Darier's disease, Grover's disease does not share an abnormality in the *ATP2A2* gene.¹²⁶² Its pathogenesis is unknown. Loss of syndecan-1 expression occurs, but this is seen in other bullous diseases. Syndecan-1 is a heparan sulfate proteoglycan present on the keratinocyte membrane; it functions in intercellular adhesion.¹²⁶³

Treatment of Grover's disease

No single agent, local or systemic, is consistently effective in the treatment of Grover's disease.¹²⁶⁴ Treatment ranges from emollients, topical corticosteroids, and topical vitamin D analogues, such as calcipotriol and tacalcitol,¹²⁶⁵ to systemic therapies such as oral corticosteroids, retinoids, and PUVA.¹²⁶⁴ In a patient with follicular lymphoma, Grover's disease remitted after treatment of the lymphoma with the anti-CD20 antibody rituximab.¹²⁶⁶

Histopathology

Early microscopic changes include elongation of rete ridges, focal acantholysis, sometimes with a few dyskeratotic keratinocytes, mild spongiosis, and a dermal infiltrate containing eosinophils.¹²⁶⁷ Four histological patterns may be seen: Darier-like,¹²³⁶ Hailey–Hailey-like, pemphigus vulgaris-like, and spongiotic (Figs. 9.23 and 9.24). The Darier pattern was the most common in one series.¹²³⁰ In a review of 72 cases from the Mayo Clinic, however, the acantholysis resembled pemphigus vulgaris in 40, Darier's disease in 16, pemphigus foliaceus in 2,

Figure 9.23 Grover's disease. A few acantholytic cells are present within the suprabasal cleft. There is a mild inflammatory infiltrate in the dermis. (H&E)

Figure 9.24 Grover's disease. There is prominent acantholysis resembling Hailey–Hailey disease. (H&E)

Hailey–Hailey disease in 2, and it was spongiotic in 12.¹²⁶⁸ The pemphigus vulgaris type was the most common histological type in the series from the Ackerman Academy of Dermatopathology.¹²⁵⁰ In the spongiotic type, there are a few acantholytic cells within and contiguous with spongiotic foci.^{1231,1236} More than one of these histological patterns may be present. In some reports, the persistent cases have tended to have either a Darier-like¹²³² or pemphigus pattern.¹²³⁴ In a recent study, several additional patterns were described: porokeratosis-like; lentiginous, resembling Dowling–Degos lesions or, in examples with acantholysis, Galli–Galli disease; vesicular; lichenoid; and a type with disordered keratinocyte maturation, somewhat resembling actinic keratosis.¹²⁶⁹ The vesicular form may have a pseudoherpetic configuration,¹²⁷⁰ we have also seen several examples of this pattern. An epidermolytic pattern has also been reported.²¹⁸ In addition to the epidermal changes, there is usually a superficial dermal infiltrate of lymphocytes and sometimes eosinophils.^{1230,1231} The presence of eosinophils in Grover's disease serves as a distinguishing feature from Darier's disease, in which they are usually absent. A neutrophilic infiltrate has also been seen in some cases.¹²⁶⁹

Older lesions may have considerable acanthosis and only subtle clefting and acantholysis (Fig. 9.25). They may be misdiagnosed as a solar keratosis or nonspecific lesion. Small, nonpigmented seborrheic

Figure 9.25 Grover's disease. (A) This lesion was of some duration and accordingly there is conspicuous acanthosis. (B) Clefting is visible in the upper layers of the epidermis in another case. Biopsies of lesions such as this are often misdiagnosed. (H&E)

keratoses seem to be increased in number¹²⁷¹ and are sometimes biopsied instead of the lesions of Grover's disease. The transient, vesiculobullous variant with a pemphigus foliaceus pattern on histology is best regarded as a variant of pemphigus foliaceus and not of Grover's disease.¹²⁷² Another histological variant, with acantholysis localized to the acrosyringium, has been reported.¹¹¹⁵ In a patient with Grover's disease and leukemia cutis, syringoma-like structures were present in the dermis.¹²⁵⁸

Direct immunofluorescence is usually negative,¹²⁴⁶ although there are several reports describing variable patterns of immunoglobulin and complement deposition.^{1231,1273,1274}

A brown, star-like dermoscopic pattern has been described in Grover's disease and acantholytic, dyskeratotic acanthoma.¹²⁷⁵

Electron microscopy

Ultrastructural changes reflect the light microscopic features with variable degrees of acantholysis, dyskeratosis, and cytoplasmic vacuolization.^{1276,1277} The dyskeratosis is represented by an increase in tonofilaments with some clumping.¹²⁷⁷ There is some loss of desmosomes in the affected area, but the hemidesmosomes of the basal layer are preserved.¹²⁷¹

Figure 9.26 Acantholytic dermatosis of the genito-crural region. The findings can be virtually identical to those of Hailey-Hailey disease, as in this case, but in some examples dyskeratosis is prominent. The clinical presentation is different, consisting of papular lesions in the aforementioned location in the absence of a family history. (H&E)

Differential diagnosis

The usual clinical presentation, together with biopsy findings of one of the four major patterns, should make the diagnosis of Grover's disease relatively straightforward. However, a biopsy showing one of the more unusual patterns could lead to confusion with porokeratosis (particularly the disseminated variety), Dowling-Degos or Galli-Galli disease, lichenoid dermatoses, actinic keratosis, herpesvirus infection, or a form of epidermolytic hyperkeratosis (e.g., epidermolytic acanthoma). In such circumstances, sampling of several lesions may be necessary because it is quite possible that one or more additional lesions might show a more 'classic' microscopic pattern. Immunostaining for herpesvirus types might also be helpful in the occasional vesicular lesion of Grover's disease that mimics this type of infection.

HAILEY-HAILEY DISEASE

Hailey-Hailey disease (familial benign chronic pemphigus; OMIM 169600) is an uncommon genodermatosis with recurrent, erythematous, vesicular plaques, which progress to small flaccid bullae with subsequent rupture and crusting.^{1278,1279} The plaques are well demarcated and spread peripherally, often with a circinate border. Rare clinical forms include papular,¹²⁸⁰ verrucous,^{1281,1282} annular, and vesiculopustular variants.¹²⁸³ Targetoid lesions resembling erythema multiforme have been reported.¹²⁸⁴ Nikolsky's sign may be positive. There is a predilection for the neck, axillae, and intertriginous areas such as the genitocrural, perianal, and inframammary region. Occasionally, large areas of the skin are involved.¹²⁸⁵ There are rare reports of involvement of oral, ocular, esophageal,¹²⁸⁶ and vaginal¹²⁸⁷ mucous membranes or of lesions limited to the vulva^{1090,1288,1289} or perianal¹²⁹⁰ region. These latter cases are best included with the cases that are now classified as 'acantholytic dermatosis of the genitocrural region' (see p. 304) (Fig. 9.26). However, a study of two cases of the latter disorder showed a novel mutation in APT2C1, encoding the Golgi hSPCA1 pump, a defect found in Hailey-Hailey disease.¹²⁹¹ Longitudinal leukonychia has been described in Hailey-Hailey disease, with parallel white stripes seen on polarized dermoscopy.¹²⁹²

Another condition with the histological features of Hailey–Hailey disease and unique clinical features is relapsing linear acantholytic dermatosis, in which there are lesions, following the lines of Blaschko, that wax and wane in a systematic pattern.¹²⁹³ Segmental Hailey–Hailey disease limited to the left inframammary area has been reported – an example of type I segmental disease.¹²⁹⁴

Hailey–Hailey disease is inherited as an autosomal dominant condition with incomplete gene penetrance. The responsible gene, *ATP2C1*, has been mapped to chromosome 3q21–q24.¹²⁹⁵ It encodes a novel Ca^{2+} pump protein hSPCA1, localized to the Golgi apparatus.^{1296,1297} It has been shown that extracellular calcium homeostasis and functioning Ca^{2+} pumps play a critical role in regulating differentiation and cell-to-cell adhesion of keratinocytes.¹²⁹⁸ Numerous different mutations have been described.^{1299–1304} Phenotypic variations do not appear to correlate with specific mutations.^{1305,1306} Nearly one-third of cases are sporadic. Onset is usually in the late teens, and there is a tendency for the disease to improve in late adulthood.¹³⁰⁷

The chronic course is punctuated by periods of spontaneous remission with subsequent exacerbations. Premenstrual exacerbations have been reported.¹³⁰⁸ Lesions may be induced in genetically predisposed tissues by trauma,^{1309,1310} patch testing,¹³¹¹ heat, ultraviolet light,¹³¹² perspiration and infection with scabies,¹³¹³ bacteria,¹³¹⁴ herpes virus,¹³¹⁵ or yeasts. HPV-6 was present in the verrucoid perineal lesions in one patient.¹³¹⁶ HPV-5 was present in a similar case.¹³¹⁷ Lesions are often mildly pruritic or burning. They are also malodorous.

Rare associations have included psoriasis,^{1309,1318,1319} Darier's disease,^{1320,1321} localized bullous pemphigoid,¹³²² syringomas of the vulva,¹³²³ squamous and basal cell carcinomas,^{1324–1326} acute generalized exanthematous pustulosis,¹³²⁷ and 'acantholytic rosacea' of the forehead and scalp.¹³²⁸ Two patients with Hailey–Hailey disease have been reported with multiple primary melanomas and other cancers.¹³²⁹

The actual mechanism of the acantholysis in Hailey–Hailey disease appears to be localized in the adherens junction region.^{1187,1330} Initially, the defect was thought to be related to a deficiency in one of the intracellular desmosomal proteins, but recent work has shown that they are all biochemically intact.¹³³¹ They may be dysfunctional in other ways. However, there is dissociation of intra- and extracellular domains of desmosomal cadherin and E-cadherin (an adherens junction-associated protein).¹¹⁸⁷ This occurs in both Hailey–Hailey and Darier's disease, but not in pemphigus.¹¹⁸⁷ There is normal expression of the gap junction proteins connexins 26 and 43 in nonlesional skin.¹³³² Haploinsufficiency is another mechanism used to explain the pathogenesis of this condition.¹³³³ Expression of *ATP2C1* mRNA is experimentally suppressed following UVB irradiation.¹³³³ This may be relevant to the clinical presentation of this disease following sunlight exposure.¹³³³ During acantholysis, there is internalization of gap junctions, but this appears to be a secondary process.¹³³² In contrast to Darier's disease, in which abnormal cell adhesion is only demonstrable in clinically involved skin, Hailey–Hailey disease is characterized by a widespread subclinical abnormality in keratinocyte adhesion.^{1330,1334} Cultured keratinocytes from patients with Hailey–Hailey disease and Darier's disease show altered calcium metabolism.¹³³⁵ Recent work has shown that SPCA1 regulates the levels of claudins 1 and 4 (important components of tight junctions) but does not affect desmosomal protein levels, suggesting a role for claudins in this disease.¹³³⁶

Dermabrasion and laser therapy have been used with success for localized disease.^{1337–1339} For generalized disease, a variety of systemic and topical agents have been used, including corticosteroids, antibiotics, antifungal agents,¹³⁴⁰ oral retinoids,¹³¹⁴ cyclosporine, or a combination of oral retinoids and cyclosporine,¹³⁴¹ dapsone, methotrexate, thalidomide, PUVA, photodynamic therapy with 5-aminolevulinic acid,¹³⁴⁰ and alefacept.¹²⁹⁸ Refractory cases have benefited by excision of affected skin and split-skin grafting using uninvolved skin.¹³⁴² Interestingly, however, if suspensions of keratinocytes from affected skin

Figure 9.27 Hailey–Hailey disease. There is suprabasal clefting with pronounced acantholysis. (H&E)

Figure 9.28 Hailey–Hailey disease with many acantholytic keratinocytes. (H&E)

are placed onto healthy heterologous dermis, devoid of its epidermis, the morphological features of the disease are reproduced *in vitro*.¹³⁴³

Histopathology

In early lesions, there are lacunae formed by suprabasilar clefting, with acantholytic cells either singly or in clumps lining the clefts and lying free within them. The lacunae progress to broad, acantholytic vesicles and bullae (Fig. 9.27). Interstitial edema leading to partial acantholysis gives rise to areas with a characteristic 'dilapidated brick wall' appearance (Fig. 9.28).¹³⁴⁴

Epidermal hyperplasia is commonly seen, and this is formed, in part, by downward elongation of the rete ridges. Elongated papillae covered by one or several layers of keratinocytes ('villi') may protrude up into the bullae.

Some acantholytic cells are dyskeratotic, but they have a well-defined nucleus and preserved cytoplasm, in contrast to the degenerating dyskeratotic cells of pemphigus. Corps ronds are infrequent, and grains are rare.

Neutrophils are sometimes numerous within the vesicles or in the surface parakeratotic crust. Bacteria may also be present in the crust.¹²⁷⁸ The dermis shows a variable, superficial chronic inflammatory cell infiltrate.

The Hailey–Hailey variant of Grover’s disease has only a narrow vesicle involving no more than a few rete ridges, in contrast to the broad lesions of Hailey–Hailey disease.¹³⁴⁴ Although pemphigus vulgaris usually has less acantholysis and some of its cells show more pronounced dyskeratosis, sometimes it can be difficult to distinguish between it and Hailey–Hailey disease without recourse to immunofluorescence.

Electron microscopy

Although earlier ultrastructural studies reported that detachment of tonofilaments from desmosomes with the subsequent disruption and disappearance of the latter was the primary event leading to acantholysis,¹³⁴⁵ subsequent studies have shown that the initial event is a series of changes in the microvilli leading to loss of cellular adhesions.^{1346,1347} Desmosomes are then separated and invaginated into cells. Thickened bundles of tonofilaments, sometimes in whorls, are found in cells of the prickle cell and granular layers.¹³⁴⁶

Differential diagnosis

The differential diagnosis of Hailey–Hailey disease includes other acantholytic dermatoses, the most important of which is pemphigus. Although both disorders show suprabasilar acantholysis, the degree of acantholysis tends to be much greater in Hailey–Hailey disease, whereas in pemphigus, often only a few acantholytic cells are usually evident in the blister cavity. It is possible to observe dyskeratosis, at least focally, in Hailey–Hailey disease, and this is not a common feature of pemphigus. Eosinophilic spongiosis is not a feature of Hailey–Hailey disease; on the other hand, eosinophils are often prominent in the dermal infiltrate of pemphigus lesions, and eosinophilic spongiosis may be identified in early lesions. Dermal eosinophils are not usually conspicuous in Hailey–Hailey disease but can be; the author has seen this on several occasions. One other major differentiating feature is follicular involvement. Although follicles are spared in Hailey–Hailey disease, they are typically involved in pemphigus and in fact may constitute a prominent feature in some examples of the latter. Direct immunofluorescence (IF) study is often decisive because positive intercellular IgG and C3 deposits are not evident in Hailey–Hailey disease but are seen in the epidermis in pemphigus.

Other acantholytic dermatoses must also be ruled out. Darier’s disease (keratosis follicularis), another genodermatosis combining acantholysis with dyskeratosis, may show overlapping features with Hailey–Hailey disease, and for a time, the latter was considered a possible blistering variant of Darier’s disease. However, in most instances, Darier’s disease displays microscopic clefts rather than bullae, and dyskeratosis is much more prominent than in Hailey–Hailey disease. The same considerations apply to other, acquired conditions showing focal acantholytic dyskeratosis, particularly Grover’s disease. The latter tends to occur in middle-aged patients as scaly papules, particularly over the trunk. That scenario is often decisive. Microscopically, the greatest difficulty vis-à-vis this particular differential is created by the forms of Grover’s disease resembling pemphigus or Hailey–Hailey disease. However, the small, self-limited nature of the lesions would ordinarily allow a confident diagnosis. A further consideration is the entity acantholytic dermatosis of the genitocrural region (papular acantholytic dyskeratosis). These localized papular lesions often have histopathologic changes identical to those of Hailey–Hailey disease, but occasionally they can have degrees of dyskeratosis more in keeping with Darier’s disease. As in Hailey–Hailey disease, direct IF studies are negative.

have a predilection for the head and neck of middle-aged and elderly individuals.^{1351,1352} A subungual and an oral lesion have also been reported.^{1353–1355} Warty dyskeratomas average 5 mm in diameter, although an unusually large example – 3 cm in diameter – has been described.¹³⁵⁶ They occasionally bleed or intermittently discharge cheesy material.¹³⁴⁹ There is no evidence of associated Darier’s or Grover’s disease.¹³⁵⁰ Polymerase chain reaction (PCR) analysis for HPV-DNA is negative.¹³⁵⁰

The lesions in comedonal Darier’s disease have the histological features of warty dyskeratoma.^{1134,1135}

Histopathology^{1349,1351}

There is a circumscribed, cup-shaped, invaginating lesion extending into the underlying dermis (**Fig. 9.29**). The central depression is filled with a plug of keratinous material containing some grains. These keratin plugs have sometimes been dislodged, particularly in oral lesions.¹³⁵⁴ The epidermal component shows suprabasilar clefting with numerous acantholytic and dyskeratotic cells within the lacuna. Protruding into the lacuna are villi, which are dermal papillae covered by a layer of basal cells. The papillae contain dilated vessels, occasional

Figure 9.29 Warty dyskeratoma. A cup-shaped invagination is filled with a keratinous plug that in turn overlies an area of suprabasilar clefting. (H&E)

WARTY DYSKERATOMA

Warty dyskeratomas (follicular dyskeratomas) are rare, usually solitary, papules or nodules with an umbilicated or pore-like center.^{1348–1350} They

melanophages, and a few inflammatory cells; inflammatory cells are also present in the underlying dermis. Pilosebaceous follicles may open into the lesion.

In a study of 46 warty dyskeratomas accessioned in Graz, Austria, three patterns were discerned on scanning magnification.¹³⁵⁰ The majority were cup-shaped, with a small number of cystic and nodular cases. Mixed patterns were also seen. The focal contiguity of many of the lesions to pilosebaceous units and the presence of differentiation toward the follicular infundibulum led the authors to propose the alternative term of 'follicular dyskeratoma' for these lesions.¹³⁵⁰

Corps ronds and grains are better developed in the skin lesions than in those in the mouth.¹³⁵⁴

The plaque-like lesion reported as '*acantholytic dyskeratotic acanthoma*' had features of both warty dyskeratoma and acantholytic acanthoma.¹³⁵⁷

HYPERGRANULOTIC DYSCORNIFICATION

Hypergranulotic dyscornification is a newly recognized pattern of epidermal dysmaturation. It is analogous to other epithelial patterns of disordered keratinization such as epidermolytic hyperkeratosis and acantholytic dyskeratosis.¹³⁵⁸ To date, the lesions reported have been solitary, scaly papules or nodules on the extremity or trunk.

The nature of this process is uncertain. The following possibilities were considered in the original article: a variant of epidermolytic hyperkeratosis, a variant of maturation in a verruca vulgaris, or a variant of the epidermolytic-like changes seen in ichthyosis hystrix of Curth-Macklin and related disorders (see p. 287).^{1358,1359} It would not be surprising to find incidental, segmental, and generalized variants of this abnormality.

Histopathology¹³⁵⁸

The lesions are exoendophytic with digitate epidermal hyperplasia with hypergranulosis. There are some similarities to a verruca vulgaris. Overlying the thickened granular layer, at the tips of the epidermal papillations, are orthokeratotic mounds of large, eosinophilic corneocytes. Keratohyalin granules are retained within these cells. There is often some basket-weave orthokeratin overlying thick and compacted orthokeratin. A pale basophilic substance is present in the higher spinous layer and granular zone. This appears to be in an intercellular location.

There is a variable lymphocytic infiltrate in the upper dermis.

COLLOID KERATOSIS

Colloid keratosis is characterized by the presence of homogeneous eosinophilic masses of variable size and number within the upper layers of squamous epithelia.¹³⁶⁰ It has been seen as an incidental finding in neoplastic and non-neoplastic lesions in the skin and respiratory tract,¹³⁶¹ as well as in pachyonychia congenita and other onychoses.¹³⁶⁰ Reports have appeared mainly in the non-English and dental literature.

It appears to result from a defect in keratinization with the accumulation of cytokeratin precursors or related protein products. Colloid keratosis has no clinical significance, and it is a reaction pattern rather than a disease entity.

Histopathology¹³⁶⁰

Homogeneous and rounded pools of eosinophilic material are found in the upper layers of the epidermis. The material is PAS positive and diastase resistant. Ultrastructurally, it is amorphous and devoid of any filaments.

Figure 9.30 Pagetoid dyskeratosis. Clear cells are scattered through the upper epidermis. (H&E)

Colloid keratosis must be distinguished from **pagetoid dyskeratosis**, which is another incidental histological finding (Fig. 9.30). It is characterized by cells with a pyknotic nucleus with a clear halo and a rim of pale cytoplasm.^{1362,1363} There is evidence that friction may be responsible for this change, at least in some cases.¹³⁶⁴ A recent example of pagetoid dyskeratosis presented as a brownish patch on a fingertip; dermoscopy revealed parallel ridge and fibrillar patterns.¹³⁶⁵ Both entities must be distinguished from clear cell papulosis (see p. 795), in which clear cells containing mucin and keratin are present in the epidermis.¹³⁶⁶ It has been suggested that the clear cells might be precursor cells for cutaneous Paget's disease.¹³⁶⁶

Differential diagnosis of pagetoid dyskeratosis

In contrast to the cells of extramammary Paget's disease, the cells of pagetoid dyskeratosis have small pyknotic nuclei and lack mucin; therefore, PAS and other mucin stains are negative. In addition, stains for cytokeratins 7 and 20 are negative in the cells of pagetoid dyskeratosis.¹³⁶⁷

DISCRETE KERATOTIC LESIONS

There is a group of rare genodermatoses of late onset in which multiple, discrete, keratotic lesions develop as a result of abnormal keratinization. This group includes hyperkeratosis lenticularis perstans, Kyrle's disease, multiple minute digitate keratoses, and waxy keratoses. Discrete keratotic lesions associated with palmar-plantar involvement or cornoid lamellation are considered elsewhere in this chapter. Certain acquired lesions such as warts, cutaneous horns, callosities, corns, stucco keratoses, solar keratoses, seborrheic keratoses, and lesions produced by tar may present as discrete keratotic lesions. They are not included in this section, which is concerned essentially with keratotic genodermatoses.

HYPERKERATOSIS LENTICULARIS PERSTANS

Hyperkeratosis lenticularis perstans (Flegel's disease; OMIM 144150)¹³⁶⁸ is a rare genodermatosis of late onset in which an abnormality in keratinization results in the development of multiple, discrete, 1- to 5-mm keratoses.¹³⁶⁹⁻¹³⁷¹ An autosomal dominant inheritance is sometimes present.¹³⁷²⁻¹³⁷⁴ The lesions are most prominent on the dorsum of the feet and the anterior aspect of the lower legs, but they

may also develop on the thighs, upper limbs, and pinnae.^{1370,1375} The keratoses develop in mid to late adult life and persist. Removal of the spiny scale causes slight bleeding.¹³⁷⁶ A unilateral variant has been described.¹³⁷⁷ This may be a manifestation of the postzygotic mosaicism seen in autosomal dominant skin disease.

Several reports, but not all,^{1375,1378} have documented a decrease in or qualitative defects of the membrane-coating granules (lamellar or Odland bodies) in affected areas of epidermis.^{1379–1383} In one study, these granules were normal in old lesions but not found in keratinocytes of early lesions.¹³⁸⁴ It has been suggested that these abnormalities are the basis for the defect in keratinization.¹³⁸⁰

No uniformly effective treatment is available. Emollients, topical 5-fluorouracil, retinoids, topical calcipotriol, and PUVA phototherapy have all been used.¹³⁸⁵

Histopathology^{1370,1375,1380}

There is a discrete zone of compact, deeply eosinophilic hyperkeratosis, with patchy areas of parakeratosis.¹³⁷⁴ There is some acanthosis at the margins of the lesions, but the epidermis at the base of the plaque of keratin is thinned with effacement of the rete ridge pattern.¹³⁷⁰ The malpighian layer may eventually be only three cells thick. The granular layer is usually less prominent in this area. There may be some basal vacuolar change¹³⁸⁶ and occasional apoptotic cells.¹³⁷⁰ They were prominent in a case reported by Hunter and Donald.¹³⁸⁷ The superficial dermis has a dense band-like infiltrate of lymphocytes, some of which appear activated (Fig. 9.31).¹³⁸¹ Some of the small lymphocytes have a nucleus with deep infoldings, resembling Sézary cells.¹³⁸⁸ Many of the cells are CD8⁺.¹³⁸³ Capillary proliferation is sometimes present. In old lesions, the epidermal atrophy is no longer present and the inflammatory infiltrate in the upper dermis is absent.¹³⁸⁴

It is tempting to speculate that the inflammatory infiltrate is an immunological reaction directed against emerging clones of abnormal epidermal cells, in much the same way that this occurs in some cases of porokeratosis.¹³⁸⁹

Electron microscopy

Studies have shown a reduction in keratohyaline granules and some persistence of desmosomal components in the stratum corneum.^{1378,1388} The disparate findings with regard to membrane-coating granules

(lamellar bodies) have been referred to previously.¹³⁷⁸ Vesicular bodies, lacking an internal lamellate structure, have been described.¹³⁸³

KYRLE'S DISEASE

The eponymous designation Kyrle's disease (OMIM 149500) is preferable to the original designation of hyperkeratosis follicularis et para-follicularis in cutem penetrans.¹³⁹⁰ This controversial entity is regarded by some as a late-onset genodermatosis in which abnormal clones of epidermal cells lead to premature keratinization at the expense of epidermal thickness, with the subsequent introduction of keratinous material into the dermis.^{1391,1392} Others regard it as a variant of perforating folliculitis – a view that is supported by the finding of perforating lesions in patients with chronic renal failure on dialysis, with clinical and histological overlap features between Kyrle's disease, perforating folliculitis, and even reactive perforating collagenosis.^{1393–1395} It has also been suggested that Kyrle's disease and Flegel's disease (hyperkeratosis lenticularis perstans; discussed previously) may be different manifestations of the same disease process.^{1396,1397}

Kyrle's disease, as traditionally described, consists of hyperkeratotic papules 2–8 mm in diameter containing a central, cone-shaped plug.^{1390,1398} The papules may be follicular or extrafollicular in location, and they may coalesce to form a verrucous plaque.¹³⁹⁹ There is a predilection for the lower limbs, but lesions may also occur on the upper limbs and less often on the head and neck.^{1398,1400} Palmar and plantar surfaces are rarely involved.^{1401,1402} Mucosal involvement is exceedingly rare.¹⁴⁰² A female preponderance has been noted in some series.¹³⁹² Onset is usually in the fourth decade. A family history has been present in a few cases.^{1392,1402} Kyrle's disease has been associated with chronic renal failure,^{1403–1405} diabetes mellitus,¹⁴⁰⁴ and, rarely, hepatic dysfunction.^{1398,1406}

Histopathology^{1407,1408}

There is a keratotic plug overlying an invaginated atrophic epidermis. Focal parakeratosis is present in part of the plug; often there is some basophilic cellular debris, which does not stain for elastin. If serial sections are studied, a focus where the epidermal cells are absent and the keratotic plug is in contact with the dermis will often be seen. An

Figure 9.31 Hyperkeratosis lenticularis perstans. (A) At scanning magnification, there is compact hyperkeratosis with depression and thinning of the underlying epidermis but mildly papillomatous borders. A band-like lymphocytic infiltrate is present in the underlying dermis. (B) In this view of a different lesion, the compact hyperkeratosis and focal band-like infiltrate are evident. (H&E)

Figure 9.32 Kyrle's disease. There is a keratin plug overlying an invaginated, atrophic epidermis (that actually represents a follicular infundibulum in this case). The plug contains parakeratosis and degenerated connective tissue and cellular debris. Transepidermal elimination can be identified at the base of the lesion on the right (arrow). The underlying dermis contains an infiltrate of lymphocytes and macrophages.

inflammatory infiltrate that includes lymphocytes, occasional neutrophils, and sometimes a few foreign body giant cells will be present in these areas. Follicular involvement may be present, particularly in those with chronic renal failure in which overlap with perforating folliculitis occurs (Fig. 9.32). Eccrine duct involvement was present in one atypical case reported in the literature.¹⁴⁰¹

In Flegel's disease, in contrast, there is massive orthokeratosis and only focal parakeratosis but no basophilic debris in the keratin layer.¹³⁹² Also, the inflammatory infiltrate is more conspicuous and usually band-like in distribution.

MULTIPLE MINUTE DIGITATE KERATOSES

Multiple minute digitate keratosis is a rare nonfollicular disorder of keratinization, also known as disseminated spiked hyperkeratosis. It can occur in four different clinical settings: a familial type with autosomal dominant inheritance,^{1409–1413} a sporadic type,^{1413–1415} a paraneoplastic variant,¹⁴¹⁶ and a postinflammatory type.^{1417,1418} Hundreds of minute keratotic spikes develop, usually in early adult life. Cases localized to the palms and soles (spiny keratoderma, palmar filiform hyperkeratosis,¹⁴¹⁹ and music-box spine keratoderma) are probably best

Figure 9.33 Spiked hyperkeratosis. The patient had disseminated spicules on her upper arms. (H&E)

classified with the palmoplantar keratodermas.^{1420–1422} There is a predilection for the upper part of the trunk and for the proximal parts of the limbs.^{1423,1424}

A closely related entity, *minute aggregate keratoses*,¹⁴²⁵ has dome-shaped papules and crateriform or annular lesions in addition to the spicular lesions seen in multiple minute digitate keratoses.

Minute keratotic spikes have been reported as an acquired phenomenon following X-irradiation,¹⁴²⁶ in Crohn's disease,¹⁴²⁷ and following the use of etretinate.¹⁴²⁸ Follicular spicules have been reported in multiple myeloma. They may be composed of proteinaceous material.¹⁴²⁹ Hair casts were present in another case.¹⁴³⁰

A solitary spiked lesion, representing a vertically growing ectopic nail, may occur on a fingertip.¹⁴³¹ An algorithm for the digitate keratoses has been proposed based on the generalized or localized nature of the process; one purpose is to consolidate the numerous synonymous terms for these conditions. Generalized forms include multiple minute digitate hyperkeratosis (nonfollicular), lichen spinulosus, and phrynodema (follicular). Localized forms include spiny keratoderma, arsenical keratosis, and multiple filiform verrucae (palmoplantar); post-irradiation digitate keratosis; and hyperkeratotic spicules, trichodysplasia spinulosa, and multiple filiform verrucae (facial).¹⁴³² The authors acknowledge that this classification may change with increased knowledge of immunohistochemical characteristics of keratins and molecular genetic studies.

Histopathology

The spicules are composed of densely compacted, thin stacks of orthokeratotic material, often arising from a finely pointed epidermal elevation. The keratinous spicules are 1–3 mm in height (Fig. 9.33). They are not related to hair follicles. There may be mild underlying epidermal hyperplasia. The dermis is normal. The digitate keratoses that develop following irradiation are characterized by parakeratotic plugs and underlying epidermal invaginations.^{1426,1433} Parakeratotic horns were also present in the patient with Crohn's disease, referred to previously.

The digitate keratoses reported from the scalp as '**congenital trichoid keratosis**' consisted of a column of corneocytes with shadow cells suggesting matrical differentiation.¹⁴³⁴

Electron microscopy

Electron microscopy shows a thickened stratum corneum and a reduced keratohyalin content in the superficial epidermis.¹⁴³⁵ Odland bodies are present.^{1409,1435}

WAXY KERATOSES

Waxy keratoses (kerinokeratosis papulosa¹⁴³⁶) are easily detachable, hyperkeratotic papules with a shiny yellowish ‘waxy’ appearance and an onset in childhood.¹⁴³⁷ The distribution is predominantly truncal, and the condition may be familial.¹⁴³⁷ A segmental form, representing mosaicism, has been reported.^{1436,1438} The associated presence of confluent hyperkeratosis at other sites is a variable feature. A recently reported case occurring in an adult has been described. The concentration on the hands, recurrences with exposure to detergents, and accompanying pruritus raised the possibility of aquagenic acrokeratoderma, although the histopathology consisted of compact orthokeratosis without a spongy configuration, and dilated eccrine ducts were not described.¹⁴³⁹

Larger papules with a mosaic pattern and acral distribution have been reported under the title ‘**mosaic acral keratosis**’.¹⁴⁴⁰

Histopathology

Waxy keratoses of childhood are characterized by marked orthokeratotic hyperkeratosis, tenting/papillomatosis of the epidermis, and some acanthosis. There is some resemblance to confluent and reticulated papillomatosis (Gougerot and Carteaud) (see p. 589); however, waxy keratoses have more prominent hyperkeratosis.

MISCELLANEOUS EPIDERMAL GENODERMATOSES

The group of miscellaneous epidermal genodermatoses includes such disparate conditions as acrokeratosis verruciformis, xeroderma pigmentosum, the ectodermal dysplasias, cutaneous and mucosal dyskeratosis, nevoid hyperkeratosis of the areola, and the peeling skin syndrome.

ACROKERATOSIS VERRUCIFORMIS

Acrokeratosis verruciformis of Hopf (OMIM 101900) is an autosomal dominant genodermatosis in which multiple papules, resembling plane warts, develop on the dorsum of the hands and fingers and, to a lesser extent, on the feet, forearms, and legs.^{1441–1445} Sporadic cases also occur.¹⁴⁴⁶ Onset is usually before puberty, but late onset has been recorded.^{1441–1444} It is more common in males.¹⁴⁴⁴ Other clinical features include punctate hyperkeratoses of the palms and nail abnormalities.¹⁴⁴⁷

Lesions identical to those of acrokeratosis verruciformis develop in a significant number of patients with Darier’s disease (see p. 305). Such lesions may precede, follow, or develop concurrently with the onset of the more usual lesions of Darier’s disease.¹⁴⁴⁸ Acrokeratosis verruciformis has been reported in the relatives of individuals with Darier’s disease.¹⁴⁴⁹ There is considerable controversy regarding the nature of the relationship of these two conditions and also about their relationship to the palmar and plantar keratoses that may accompany either disease. One view is that the acral lesions of Darier’s disease and acrokeratosis verruciformis are separate entities.¹⁴⁴⁴ This is based on the finding of small foci of acantholytic dyskeratosis in some acral keratotic lesions of Darier’s disease if multiple sections are examined. This is also supported by a finding that there is genetic heterogeneity in acrokeratosis verruciformis. In one Chinese study, no evidence of any linkage to the *ATP2A2* gene on chromosome 12q23–q24 was found.¹⁴⁴⁷ The contrary view is that both diseases result from a single autosomal dominant genetic defect with variable expressivity of the gene.^{1448,1450,1451} This latter theory was supported by the finding in 2003

of a mutation in the *ATP2A2* gene in two patients from a British family with acrokeratosis verruciformis, indicating that it is allelic to Darier’s disease.¹⁴⁵² As previously stated, a Chinese study found no such link.¹⁴⁴⁷ In a recent report, a patient with sporadic acrokeratosis verruciformis was found to have a heterozygous A698V mutation in *ATP2A2*.¹⁴⁵³ In another study involving a family with acrokeratosis verruciformis, a heterozygous P602L mutation in *ATP2A2* was identified.¹⁴⁵⁴ Still another patient with late-onset Darier’s disease was found to have a missense mutation at position 698 (A698P), affecting the same codon as previously reported in acrokeratosis verruciformis.¹⁴⁵⁵ These findings tend to strengthen the argument that Darier’s disease and acrokeratosis verruciformis are allelic disorders with variable expressivity.

Histopathology^{1441,1444}

Sections show hyperkeratosis, regular acanthosis, and low papillomatosis, imparting a regular undulating appearance to the surface (Figs. 9.34 and 9.35). These changes have been likened to ‘church spires’. There

Figure 9.34 Acrokeratosis verruciformis. There is low papillomatosis (‘church spiring’). Multiple lesions were present, but there were no features of Darier’s disease. (H&E)

Figure 9.35 Acrokeratosis verruciformis in a patient with Darier’s disease. There is compact orthokeratosis and low papillomatosis imparting an undulating appearance to the epidermis. There is a small focus of acantholytic dyskeratosis. (H&E)

Figure 9.36 Acrokeratosis verruciformis. This example, with suprabasilar acantholysis and dyskeratosis with corps ronds formation, occurred in a patient without clinical evidence of Darier's disease. (H&E)

is no parakeratosis, no epidermal vacuolation, and no significant dermal inflammatory infiltrate. We have encountered an adult patient with acrokeratosis verruciformis who lacked evidence for Darier's disease but still featured suprabasilar acantholysis and dyskeratosis in her lesions (**Fig. 9.36**). Similar findings were reported in two of the previously mentioned patients with acrokeratosis verruciformis having the P602L mutation.¹⁴⁵⁴

Squamous cell carcinomas have been reported in two cases of long standing.¹⁴⁴⁴

XERODERMA PIGMENTOSUM

Xeroderma pigmentosum is a rare, autosomal recessive genodermatosis characterized by deficient DNA repair, photophobia, severe solar sensitivity, cutaneous pigmentary changes, xerosis, and the early development of mucocutaneous and ocular cancers, particularly in sun-exposed areas.¹⁴⁵⁶⁻¹⁴⁶⁴ Dermoscopy has been used to monitor skin lesions in this condition.¹⁴⁶⁵ Neurological abnormalities are present in up to 20%,¹⁴⁶⁶ and these are most severe in the De Sanctis-Cacchione syndrome (microcephaly, dwarfism, choreoathetosis, and mental deficiency; OMIM 278800),^{1456,1458,1467} which in most cases is associated with the XP-A variant of xeroderma pigmentosum. The earliest changes in xeroderma pigmentosum usually develop before the age of 2 years with a severe sunburn reaction and the development of multiple freckles with variable intensity of melanin pigmentation and interspersed hypopigmented macules.¹⁴⁶⁸ Pigmentation often develops on the palms and soles and mucous membranes. Later, there is dry, scaly skin (xerosis) with poikilodermatous features. Skin tumors, which include solar keratoses, cutaneous horns, keratoacanthomas, squamous and basal cell carcinomas, basosquamous carcinoma, atypical fibroxanthoma,¹⁴⁶⁹ malignant melanomas,¹⁴⁷⁰ and angiomas, may develop in late childhood; patients may ultimately die from the consequences of their tumors.¹⁴⁶⁶ The development of the cutaneous lesions can be retarded by protection from the sun from birth.^{1080,1471} Immunological abnormalities have been present in some patients.¹⁴⁷² Unexpected findings include pyogenic granulomas, desmoplastic melanomas, and multinodular thyroid.¹⁴⁷³

Xeroderma pigmentosum involves both sexes and all races with an incidence of 1:250,000 and a gene frequency of 1:200.¹⁴⁵⁶ There is a

high incidence of consanguinity.^{1474,1475} Until recently, heterozygotes could not be reliably demonstrated in the laboratory.¹⁴⁷⁶ They are asymptomatic, although there is one report of an increased incidence of malignant skin tumors in these individuals.¹⁴⁵⁶ Prenatal diagnosis of xeroderma pigmentosum can be made by an analysis of DNA repair in cells cultured from the amniotic fluid of women at risk.¹⁴⁷⁷

There is genetic heterogeneity with at least nine different groups recognized by somatic cell fusion studies – so-called ‘complementation groups’.^{1456,1478} Seven of these groups (labeled A–G) have deficient excision repair of ultraviolet radiation-induced DNA damage (particularly nucleotide excision repair),¹⁴⁷⁹ whereas in one (the so-called ‘XP variant’) there is defective ability to convert newly synthesized DNA from low to high molecular weight after UV irradiation (postreplication repair).^{1456,1480-1482} These different complementation groups have different clinical correlations, including differing susceptibility to the various cutaneous tumors.¹⁴⁸³ For example, XP-A is the most severe form, and some of this group have the De Sanctis-Cacchione syndrome (discussed previously). The severity of the neurological abnormalities in Japanese patients in this group correlates with the sites of nonsense mutations in the XP-A gene.¹⁴⁸⁴ XP-C and XP-D genes are associated with susceptibility to melanoma.¹⁴⁸⁵ XP-E is the mildest form, with late onset and a higher residual capacity to repair UV-induced DNA damage in *in vitro* studies.^{1486,1487} XP-F,¹⁴⁸⁸⁻¹⁴⁹⁰ XP-G,¹⁴⁹¹ and XP-B are extremely rare; the latter group has in some cases been associated with the Cockayne syndrome (short stature, photosensitivity, deafness, mental deficiency, large ears and nose, and sunken eyes).^{1456,1459,1492-1498} The gene responsible for the severe type 2 Cockayne syndrome (OMIM 133540) is the excision repair cross-complementing group 6 (*ERCC6*) gene, located on chromosome 10q11, but the classic type 1 Cockayne syndrome (OMIM 216400) is due to mutations in *ERCC8* on chromosome 5q12. XP-C is the most prevalent form of xeroderma pigmentosum among North Americans and Europeans.¹⁴⁹⁹ Squamous cell carcinomas are commonly found in group A, basal cell carcinomas in groups C and E and in the variant form, and malignant melanomas in groups C and D and also in the variant form.^{1456,1500-1502} Among black XP-C patients in the Mayotte population in the Indian Ocean, a new G–C gene splicing mutation has been found, associated with early onset of severe cutaneous and ocular abnormalities.¹⁵⁰³ A new disorder with defective DNA repair distinct from xeroderma pigmentosum or Cockayne syndrome, and associated with UV-induced skin cancers, has been reported.¹⁵⁰⁴ Trichothiodystrophy can have overlapping genetic defects with XP (XP-B and XP-D), but despite significant developmental abnormalities, there is not an increase in skin cancer development.¹⁵⁰⁵ Patients with overlap of the two syndromes do occur; interestingly, they have hair shaft defects that are less prominent than those in pure trichothiodystrophy and also a risk for cutaneous malignancies that is somewhat less than that seen in XP.¹⁵⁰⁵

In one study, a skin fibroblast cell strain from a patient with xeroderma pigmentosum was reported to have shown spontaneous morphological transformation to an anchorage-independent form after serial passage.¹⁵⁰⁶ This presumably has some significance in the development of tumors *in vivo*; the finding of reduced natural killer cell activity may have a similar significance.¹⁵⁰⁷

It is now well-established that cultured fibroblasts from patients with xeroderma pigmentosum show defective DNA repair following ultraviolet irradiation. This abnormality is also present in keratinocytes and melanocytes cultured from affected patients.¹⁵⁰⁸ Cultured keratinocytes from patients with xeroderma pigmentosum are more sensitive than normal cells to UVB-induced apoptosis.¹⁴⁷⁹ The DNA nucleotide excision repair pathway involves at least 28 genes, 11 of which have been associated with clinical diseases.¹⁵⁰⁹ The defect in xeroderma pigmentosum involves an initial phase in the process of excision repair.¹⁵¹⁰ Radiation therapy has been used successfully in the treatment of high-risk squamous cell carcinomas in XP patients; it

Table 9.5 Types of xeroderma pigmentosum (XP)			
Type	OMIM	Gene defect	Gene locus
XP-A	278700	<i>XPA</i>	9q22.3
XP-B	133510	<i>XPB (ERCC3)</i>	2q21
XP-C	278720	<i>XPC</i>	3p25
XP-D	278730	<i>XPD (ERCC2)</i>	19q13.2–q13.3
XP-E	278740	<i>XPE (DDB2)</i>	11p12–p11
XP-F	278760	<i>XPF (ERCC4)</i>	16p13.3–p13.13
XP-G	278780	<i>XPG (ERCC5)</i>	13q33
XP variant	278750	<i>POLH</i>	6p21.1–p12
De Sanctis–Cacchione syndrome	278800	<i>XPA/ERCC6</i>	9q22.3/10q11

appears that XP patients generally have normal responses to ionizing irradiation, underscoring the specificity of their ultraviolet-induced nucleotide excision repair defect.¹⁵¹¹ There is evidence that melanocyte-stimulating hormone enhances DNA repair in keratinocytes by binding to melanocortin receptor type 1, activating adenylate cyclase activity, which then activates XP-A binding protein 1, inducing nuclear translocation of XP-A; this is a key factor in controlling nucleotide excision repair signaling pathways.¹⁵¹²

All the genes for xeroderma pigmentosa have now been cloned. The gene responsible for xeroderma pigmentosum group A (XP-A) has been cloned and designated the *XPA* gene. At least 20 mutations of this gene exist, resulting in a different clinical severity for each mutation group.^{1476,1513–1515} The various genes involved in each of the types of xeroderma pigmentosum are listed in Table 9.5.

Absolute sun protection is the key to the management of this condition.

Histopathology¹⁴⁵⁷

In the initial stages, there are no diagnostically specific features. There may be variability in epidermal melanin concentration, telangiectasia of superficial vessels, and a mild perivascular inflammatory cell reaction. With time, the pigmentary changes are more marked, with areas of prominent melanin pigmentation of the basal, malpighian, and spinous layers and pigmentary incontinence. Areas of hypopigmentation, sometimes with epidermal atrophy, may be seen. There is eventually prominent solar elastosis and the development of areas of hyperkeratosis. Keratoses and the other tumors already mentioned eventually develop. Tumors of the anterior part of the tongue have also been reported.¹⁵¹⁶ Ki-67 expression in basal cell and squamous cell carcinomas from XP patients is significantly higher than that in non-XP patients and may be a reflection of the biologic aggressiveness of these tumors.¹⁵¹⁷ Increased Ki-67 and PCNA expression may predict recurrence of nonmelanocytic skin cancers in these patients and portend a poor prognosis.¹⁵¹⁸ Ophthalmic abnormalities include pinguecula formation, corneal pannus, exposure keratopathy, as well as retinal gliosis and other retinal changes.¹⁵¹⁹

Electron microscopy

Various changes have been noted, including irregular nuclear morphology, melanosomes with a high degree of polymorphism, and dilated rough endoplasmic reticulum, vacuoles, and disrupted desmosomes in basal keratinocytes.¹⁵²⁰ Fibroblast-like cells may show melanophagic activity.¹⁵²⁰ Structures resembling anchoring fibrils and the basal lamina have been noted in the dilated endoplasmic reticulum of these cells.¹⁵²¹

ECTODERMAL DYSPLASIAS

The ectodermal dysplasias are an expanding but nevertheless rare group of genodermatoses characterized by a diffuse, nonprogressive disorder of the epidermis and at least one of its appendages.^{1522,1523} The epidermal component may involve keratinocytes, melanocytes,¹⁵²⁴ or Langerhans cells or any combination thereof; the ‘appendageal’ component may affect the hair, sebaceous or eccrine glands, the nails, or the teeth.¹⁵²⁵ The ectodermal dysplasias comprise approximately 200 clinically distinct syndromes, and the limits of this entity are not clearly defined.^{1526,1527} Their incidence in the United States is approximately 1:100,000 births.¹⁵²⁸ Abnormalities of non-ectodermal structures may also be present.

The traditional classification of the ectodermal dysplasias into hidrotic and anhidrotic types is not appropriate for the broad range of abnormalities that may occur in this group. They are now classified on the basis of the presence or absence of trichodysplasia,¹⁵²⁹ dental abnormalities, onychodysplasia, and dyshidrosis. Sometimes more than one such abnormality is present, such as the odonto-onycho-dermal dysplasia syndrome (OMIM 257980), which also includes dystrophic nails, hyperhidrosis, palmoplantar keratoderma, and atrophic patches on the malar area.¹⁵³⁰ Other examples are cranioectodermal dysplasia (OMIM 218330) with craniofacial and skeletal anomalies, including dental anomalies,¹⁵³¹ and Ellis–van Creveld syndrome (OMIM 225500) due to mutations in the *EVC* gene on chromosome 4p16.^{439,1532} It combines chondrodystrophy with central nervous system and urinary anomalies. There may also be dystrophic nails, partial adontia, and multiple frenulae.¹⁵³² The Naegeli–Franceschetti–Jadassohn syndrome (OMIM 161000) affects sweat glands, nails, teeth, and skin. It includes reticulate pigmentation of the skin as an important component and is therefore discussed with other disorders of pigmentation (see p. 340). The gene maps to chromosome 17q21 in the region of the type 1 keratin gene cluster.¹⁵³³ Another ectodermal dysplasia, this time with pure hair and nail disturbances (OMIM 602032), is due to a defect in the keratin basic hair protein 5 (*KRTHB5*) gene on 12q13.¹⁵³⁴ A novel locus has also been described on chromosome 17p12–q21.2.¹⁵³⁵ The autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy syndrome (OMIM 240300) is due to mutations in the autoimmune regulator (*AIRE*) gene.¹⁵³⁶ Alopecia areata and vitiligo may also be present. Most of the syndromes are extremely rare and of little dermatopathological importance.¹⁵³⁷ Six of them merit further discussion.

Anhidrotic (hypohidrotic) ectodermal dysplasia

In anhidrotic (hypohidrotic) ectodermal dysplasia (OMIM 305100), an X-linked recessive disorder also known as the Christ–Siemens–Touraine syndrome, there is anhidrosis or marked hypohidrosis, complete or partial anodontia, hypotrichosis, and a characteristic facies.^{771,1538–1541} Less frequent manifestations include nail dystrophy, genital anomalies, collodion membrane,¹⁵⁴² neuroblastoma,¹⁵⁴³ the absence of mammary glands, palmoplantar keratoderma,¹⁵⁴⁴ impaired immunity,¹⁵⁴⁵ and mental retardation.^{1546,1547}

Immune dysfunction is seen in two genetically distinct syndromes. In one (OMIM 300291), there is a mutation in the *NEMO* gene on Xq28.¹⁵⁴⁸ In one case, it was accompanied by incontinentia pigmenti, the usual manifestation of this mutation involving the NF-κB pathway.¹⁵⁴⁹ The other (OMIM 164008) involves the NFκ light-chain gene enhancer in B cells inhibitor (*NFKBIA*) gene at 14q13.⁴³⁹

A prenatal diagnosis of anhidrotic (hypohidrotic) ectodermal dysplasia can be made by an examination of fetal skin¹⁵⁵⁰ or by newer PCR-based methods. Female carriers may show reduced sweating and faulty dentition.¹⁵⁵¹ Detecting them can be difficult.¹⁵⁵² The gene responsible (*ED1*, *EDA*) is localized at Xq12–q13.1.^{439,1553–1558} It affects

a transmembrane protein expressed by keratinocytes, hair follicles, and sweat glands.¹⁵⁵⁹ Numerous mutations in this gene have already been described.¹⁵⁵⁸ The gene responsible for the less frequent autosomal recessive form (OMIM 224900) maps to chromosome 2q11–q13.¹⁵⁵⁹ It involves the ectodysplasin anhidrotic receptor (*EDAR*) gene.^{1555,1560,1561} It is now believed that four genes account for 90% of cases of hypohidrotic/anhidrotic ectodermal dysplasia. *EDA1* is responsible for the X-linked variety, *EDAR* for autosomal dominant and recessive forms, *EDARADD* for the autosomal recessive form (and one dominantly inherited missense mutation), and the *WNT10A* gene is involved in several autosomal recessive forms of ectodermal dysplasia. Whereas no significant clinical differences are associated with mutations of the first three genes, *WNT10A* mutations have distinctive features, including microdontia, abnormal sweating, and absent facial dysmorphism.¹⁵⁶²

Ectodermal dysplasia/skin fragility syndrome

This syndrome (OMIM 604536), described by McGrath *et al.* in 1997,¹⁵⁶³ is an autosomal recessive disorder characterized by trauma-induced skin fragility and blistering, palmoplantar keratoderma, abnormal hair growth, perioral erosions, nail dystrophy, and often defective sweating (hypohidrosis).^{618,1564,1565} It results from mutations in the *PKP1* gene at 1q32, encoding the desmosomal plaque protein plakophilin 1.¹⁵⁶⁶ This protein is preferentially expressed in the outer root sheath of hair follicles, but no hair shaft abnormalities have been described.⁶¹⁸ Preimplantation diagnosis of this syndrome can be made.¹⁵⁶⁷

Hidrotic ectodermal dysplasia

The hidrotic, autosomal dominant variant of ectodermal dysplasia (Clouston's syndrome; OMIM 129500) is characterized by the triad of alopecia, dystrophic nails, and palmoplantar keratoderma.^{1522,1568–1571} Dental abnormalities may also be present, but sweating is normal, in contrast to many other ectodermal dysplasias.

Mutations in the *GJB6* gene, at 13q11–q12.1, encoding the gap junction protein connexin 30 have been shown to cause this disorder.^{1572–1575} The patient who presented with alopecia, nail dystrophy, palmoplantar hyperkeratosis, keratitis, hearing difficulty, and micrognathia without *GJB6* mutations may represent a new type of hidrotic ectodermal dysplasia.¹⁵⁷⁶ A G11R mutation in the *GJB6* gene in a Chinese family has been associated with involvement limited to hair and nails.¹⁵⁷⁷

Orofaciodigital syndrome

Orofaciodigital syndrome type 1 (OMIM 311200) is an X-linked dominant disorder that is usually lethal in males.^{1522,1578} It is due to a mutation in the *CXORF5* or *OFD1* gene at Xp22.3–p22.2. There is a marked reduction in sebaceous glands on the scalp or face, dental dysplasia, evanescent facial milia, cleft lip and palate, and malformation of the digits, including Y-shaped metacarpals in the type VI Varadi–Papp syndrome.¹⁵⁷⁹ Mental retardation may be present. Phenotypically related syndromes include digitocutaneous dysplasia (terminal osseous dysplasia with pigmentary defects; OMIM 300244), characterized by bone anomalies, dental anomalies, dysmorphic features, digital fibromas, atrophic plaques and pigmented skin lesions, and X-linked dominant inheritance.¹⁵⁸⁰ It is due to mutations in a gene on Xq27.3–q28.¹⁵⁸⁰ Another related syndrome is oculodentodigital dysplasia (OMIM 164200) due to mutations in the *GJA1* gene that encodes connexin 43.

Cardiofaciocutaneous (CFC) syndrome

This syndrome (OMIM 115150) is characterized by congenital heart defects, cutaneous abnormalities, and distinctive facial features bearing

some resemblance to Noonan syndrome (OMIM 163950).^{1581–1583} Mild to severe mental retardation is usually present. A case with hemihidrosis has been reported, indicating that this syndrome, although not usually included with the ectodermal dysplasias, does meet the criteria for this category of diseases.¹⁵⁸⁴ Nearly 100 cases have been reported.

The Costello syndrome (OMIM 218040), which also has phenotypic overlap, has a mutation in the *HRAS* (the Ras Harvey rat sarcoma) gene on 11p15.5.¹⁵⁸⁵ Mutations in *BRAF*, *MEK1*, and *MEK2* also appear to be associated with the CFC phenotype.¹⁵⁸⁶ *BRAF* mutations are more common than *MEK1* (*MAP2K1*) or *MEK2* (*MAP2K2*) mutations. *MEK* mutations are associated with a milder phenotype.¹⁵⁸⁵ The phenotype associated with *KRAS* mutations is highly variable and may be suggestive of Noonan syndrome (sometimes called Noonan syndrome type 3 (OMIM 609942) to distinguish it from type 1 (OMIM 163950)), which is due to mutations in the protein tyrosine phosphatase nonreceptor type 11 (*PTPN11*) gene on 12q24.1.⁴³⁹ Mutations in the *SOS-1* gene are also involved in Noonan syndrome. There is a phenotypic continuum between the CFC syndrome and Noonan syndrome.¹⁵⁸⁵ Key cutaneous features associated to varying degrees with *BRAF*, *MAP2K1*, and *MAP2K2* mutations include keratosis pilaris, callouses on hands and feet, hemangiomas, curly hair, and sparse or absent eyebrows.¹⁵⁸⁷

Ectodermal dysplasias with clefting

There are several clinical syndromes characterized by ectodermal dysplasia in association with clefting of the lip and/or palate. Vegetative, hyperkeratotic plaques develop over the oral commissures and the mid-portions of the lips.¹⁵⁸⁸ Many of them seem to be caused by different mutations in the *p63* gene on 3q27.^{1528,1589–1592} They include the EEC syndrome (ectodermal dysplasia, ectodactyly, cleft lip/palate; OMIM 604292 and 129900),^{1593,1594} the Rapp–Hodgkin syndrome¹⁵⁹⁵ (the additional clinical feature is facial hypoplasia; OMIM 129400), and the Hay–Wells or AEC syndrome (the additional clinical feature is ankyloblepharon, but skin fragility¹⁵⁹⁶ is often present as well; OMIM 106260).^{1592,1597–1606} They are allelic.¹⁶⁰⁷ Another mutation within the DNA-binding domain of *p63* produces ADULT (*acro-dermato-ungual-lacrimar-tooth*) syndrome (OMIM 103285).¹⁶⁰⁸ Closely related syndromes include Bowen–Armstrong (OMIM 225000) and CHAND (OMIM 214350) syndromes.¹⁶⁰⁹

Histopathology of the ectodermal dysplasias

The histological features will obviously vary according to which epidermal and appendageal components are involved.

In *anhidrotic ectodermal dysplasia*, the epidermis is thinned. Eccrine glands are absent or rudimentary, although poorly formed intraepidermal eccrine ducts may be present.¹⁶¹⁰ Sweat glands are more likely to be absent in scalp skin than in palmar skin.¹⁶¹¹ Apocrine glands may also be hypotrophic. There is a reduction in pilosebaceous follicles, although, paradoxically, foci of sebaceous hyperplasia have sometimes been noted on the upper cheeks.¹⁶¹² Other reported features include a reduction in seromucous glands in the respiratory tract,¹⁶¹³ a reduction in epidermal Langerhans cells, and fragmentation of dermal elastic fibers. Because eccrine glands do not develop until 20–24 weeks of gestation, whereas hair follicles should be present at this time, it is the absence of pilar units that is used to make the diagnosis on fetal skin biopsies taken during this period of gestation.¹⁵⁵⁰

In the *ectodermal dysplasia/skin fragility syndrome*, there is a widening of spaces between keratinocytes in the upper spinous layers with dysadhesion and detachment of the upper epidermal layers. There are some suprabasal clefts. Although described as acantholysis,¹⁶¹⁴ it is slightly different, with the plane of cleavage occurring immediately on the cytoplasmic side of desmosomes in keeping with the intracellular distribution of plakophilin 1.⁶¹⁸ There may be dyskeratotic cells in the

keratoderma and an increase in catagen/telogen hair follicles.¹⁶¹⁴ With direct immunofluorescence staining, there is significant reduction in staining for plakophilin 1.¹⁶¹⁵

In *hidrotic ectodermal dysplasia*, there is pronounced hyperkeratosis, particularly of the palms and soles, a normal granular layer, and a normal number of sweat glands. The sweat glands are also normal in number in the *orofaciocutaneous syndrome*, but sebaceous glands are diminished or absent.¹⁵⁷⁸ The epidermis may be somewhat atrophic. No specific histological features have been described in the *cardiofaciocutaneous syndrome*.

In *ectodermal dysplasias with clefting*, the pilosebaceous follicles are reduced in size and small vellus follicles are present.¹⁵⁹⁸ A scalp dermatitis with variable histological changes may be present.

CUTANEOUS AND MUCOSAL DYSKERATOSIS

There has been a report describing a father and son with brownish papules with central keratotic plugs.¹⁶¹⁶ Single cell keratinization (dyskeratosis) was present in the epidermis, as well as in the epithelium of the mouth and the conjunctiva.¹⁶¹⁶ A similar condition has been called hereditary benign intraepithelial dyskeratosis. There were prominent oral lesions.¹⁶¹⁷ In another case, numerous dyskeratotic cells were present in epithelium of the lips, palate, and gums and on the labial surfaces of the genitalia, as an acquired phenomenon: this condition was referred to as acquired dyskeratotic leukoplakia.¹⁶¹⁸ Dyskeratotic cells were also a feature of the cases reported as hereditary mucoepithelial dysplasia (HMD).¹⁶¹⁹ HMD is characterized by the triad of nonscarring alopecia, well-demarcated erythema of oral mucosa, and psoriasiform perineal rash.¹⁶²⁰ No genetic mutations have been found, but many have been excluded.¹⁶²⁰

NEVOID HYPERKERATOSIS OF THE NIPPLE

The rare condition nevoid hyperkeratosis of the nipple and areola is manifest by hyperpigmentation of the areola with accompanying verrucous thickening.¹⁶²¹ More than 50 cases have been reported. It may be unilateral or bilateral.¹⁶²²⁻¹⁶²⁴ Similar, but usually milder, changes may be seen in Darier's disease, pregnancy, and, rarely, in men receiving estrogen therapy for prostatic adenocarcinoma.¹⁶²⁵ Its association with acanthosis nigricans is well documented.^{1626,1627} Cases unrelated to estrogen therapy have been reported in males.^{1628,1629} It has also been reported in a patient with incomplete androgen insensitivity syndrome (46XY karyotype) on estrogen replacement therapy.¹⁶³⁰

There are no trials on the treatment of this condition. All reports are anecdotal. Cryotherapy and topical keratolytics have been used, but agents such as 40% urea, 12% lactic acid lotion, and topical retinoids have given mixed or poor results.¹⁶³¹ Several cases have responded well to calcipotriol.^{1626,1632} Radiofrequency ablation has been used successfully in a case of unilateral nevoid hyperkeratosis of the nipple and areola.¹⁶³³

Histopathology

There is hyperkeratosis, papillomatosis, and acanthosis with marked elongation of the rete ridges, the latter often having a filiform interconnecting pattern (Fig. 9.37). Keratin-filled spaces and ostia are also present.^{1625,1634} There is a superficial resemblance to a seborrheic keratosis but with a more delicate, interconnecting acanthosis.¹⁶³⁵ In another case, there was a resemblance to nevus comedonicus.¹⁶³⁶

PEELING SKIN SYNDROME

The peeling skin syndrome (OMIM 270300) is a rare autosomal recessive disorder characterized by spontaneous, continual peeling of the

Figure 9.37 Nevoid hyperkeratosis of the nipple. Findings include focal hyperkeratosis, papillomatosis, and acanthosis with marked elongation of the rete ridges. (H&E)

skin.^{1637,1638} Variants in which the peeling has been localized to the palm,¹⁶³⁹ face,¹⁶⁴⁰ or acral regions^{1641,1642} have been reported. The acral variant (OMIM 609796) is caused by a homozygous mutation in the transglutaminase-5 (*TGM5*) gene¹⁶⁴³ or the *CSTA* gene encoding cystatin A.¹⁶⁴⁴ Azathioprine has been associated with a clinical simulant. Aminoaciduria was present in another case.¹⁶⁴⁵

Generalized peeling skin syndrome has been divided into three types: type A consists of asymptomatic, non-inflammatory peeling; type B represents congenital ichthyosiform erythroderma with erythematous migrating patches, peeling borders, pruritus, and atopy; and type C begins in infancy and manifests as erythematous patches with a surrounding, peeling collarette, associated with blepharitis, conjunctivitis, and cheilitis.¹⁶⁴⁶ Generalized inflammatory peeling skin syndrome has been associated with recessively inherited loss-of-function mutations in the *CDSN* gene.¹⁶⁴⁷ Type B by description sounds very much like Netherton's syndrome, and in fact a recent case initially diagnosed as generalized inflammatory peeling skin syndrome turned out to be an example of Netherton's syndrome, characterized by a homozygous splice site mutation of the *SPINK5* gene.²⁵⁶ The authors suggested a functional relationship between these two disorders. The *SPINK5* gene encodes a serine protease inhibitor LEKT1 (lymphoepithelial Kazal-type-related inhibitor). Disruption of LEKT1 is associated with upregulation of kallikrein-related peptidases, with excessive desquamation due to premature proteolysis of structural proteins that include the product of the *CDSN* gene, corneodesmosin.²⁵⁶

Erythrokeratolysis hiemalis (keratolytic winter erythema, Oudtshoorn disease; OMIM 148370), a rare autosomal dominant genodermatosis with seasonal variation, is common in South Africa and related to an abnormality in chromosome 8p22-p23. It is also characterized by foci of erythema and skin peeling.²⁶⁸ Spontaneous mutations appear to occur.¹⁶⁴⁸

Histopathology

There is hyperkeratosis, parakeratosis, reduction of the granular layer, and acanthosis. There is separation of the stratum corneum from the underlying granular layer.^{1637,1649} This description applies to localized and type A generalized peeling skin syndromes (Fig. 9.38). Generalized type B shows absence of stratum corneum or a few separated parakeratotic layers, sometimes associated with psoriasiform acanthosis

Figure 9.38 Peeling skin syndrome. (A) There are hyperkeratosis, reduction in the granular cell layer, and acanthosis. The stratum corneum has separated from the underlying epidermis. (B) For this image, the stratum corneum was partly peeled away from the underlying epidermis prior to biopsy. These changes are seen in localized and type A generalized forms of peeling skin syndrome. (H&E)

and perivascular round cell infiltrates. Generalized type C lesions resemble those of type B disease.¹⁶⁴⁶

In *erythrokeratolysis hiemalis*, there is ‘necrobiosis’ of keratinocytes in the malpighian layer, although only hyperkeratosis and acanthosis were present in another case.¹⁶⁵⁰

Electron microscopy

Keratohyaline granules are poorly formed and keratin filaments are incompletely aggregated below the level of the split.¹⁶⁴² Intra- and intercellular cleavage of corneocytes and intracellular separation of granular cells are also present.¹⁶⁵¹

MISCELLANEOUS DISORDERS

Only three conditions are considered in this section: granular parakeratosis, circumscribed acral hypokeratosis, and white sponge nevus.

GRANULAR PARAKERATOSIS

Granular parakeratosis is an acquired abnormality of keratinization first described in 1991 as axillary granular parakeratosis.^{1652–1655} It has since been described in other intertriginous areas, such as the inguinal region,¹⁶⁵⁶ inter- and submammary region,¹⁶⁵⁷ the vulva and perianal region.^{1653,1657} Multiple intertriginous areas may be involved simultaneously.¹⁶⁵⁸ Rare cases involving the abdomen and the knee have been seen, indicating that the adjectives ‘axillary’ and ‘intertriginous’ are both inappropriate in the title. Most cases occur in adults, but children may also be involved.^{1659–1662} Also, a congenital case with inguinal involvement has been reported.¹⁶⁶³ There is a female predominance.¹⁶⁶⁴ The lesions are scaly red to hyperpigmented plaques that are often pruritic.¹⁶⁶⁵ Sometimes the lesions appear macerated.¹⁶⁶⁶ Rarely, they are papillomatous.¹⁶⁶⁴ Axillary lesions can resemble acanthosis nigricans. A case of granular parakeratosis of eccrine ostia presented with small pruritic papules on the face and neck,¹⁶⁶⁷ and another case displayed brownish verrucous papules on the neck.¹⁶⁶⁸

Granular parakeratosis has been observed as an incidental finding overlying molluscum contagiosum¹⁶⁶⁹ and also in association with dermatomyositis,¹⁶⁷⁰ dermatophyte infection,¹⁶⁷¹ and cutaneous carcinomas.¹⁶⁷² It has also developed in a woman with ovarian carcinoma treated with liposomal doxorubicin.¹⁶⁷³ The lesions spontaneously regressed after 4 weeks.

The cases reported by Resnik and colleagues as **granular parakeratotic acanthoma** were regarded as akin to epidermolytic acanthoma and acantholytic dyskeratotic acanthoma.¹⁶⁷⁴ If this analogy is accepted, then the cases reported are worthy of acceptance and not dismissible as seborrheic keratoses as suggested by Wang *et al.*¹⁶⁶⁷

There appears to be a defect in the processing of profilaggrin to filaggrin that results in a failure to degrade keratohyaline granules.¹⁶⁵³ The etiology is unknown. Suggestions that the condition may result from excess use of topical antiperspirants seem difficult to sustain in cases occurring outside the axilla.¹⁶⁷⁵ Mechanical irritation may also play a role in inducing these skin changes.^{1676,1677} In several childhood cases, the mothers all reported the habit of frequent washing followed by application of many topical products.¹⁶⁶¹ Diaper wearing or the treatment of diaper rashes appears to play an important role in the genesis of infantile cases.^{1662,1678}

Granular parakeratosis usually clears spontaneously after months to 1 year.¹⁶⁷⁸ It has cleared rapidly following the topical use of tretinoin.¹⁶⁷⁹ Other treatments used include 40% urea cream,¹⁶⁶⁴ topical calcipotriene and ammonium lactate,¹⁶⁸⁰ and a combination of 1% hydrocortisone cream and 1% clotrimazole cream.¹⁶⁵⁸

Histopathology

There is a thick parakeratotic layer with retention of keratohyaline granules in this region (**Fig. 9.39**). The stratum granulosum is also preserved. The underlying epidermis may be normal, mildly atrophic, or show psoriasiform acanthosis. The process has also involved the follicular infundibulum¹⁶⁸¹ and the eccrine ostia.¹⁶⁶⁷ No hair follicles were involved in this latter case.¹⁶⁶⁷

CIRCUMSCRIBED ACRAL HYPOKERATOSIS

Originally described in 2002 as circumscribed palmar or plantar hypokeratosis by Pérez and colleagues,¹⁶⁸² the word ‘acral’ was suggested by Berk *et al.* in 2007 as a shortened title.¹⁶⁸³ It has merit. This entity has a predilection for the thenar and hypothenar aspects of the palm and, much less commonly, the medial side of the sole.^{1682,1684} Lesions present as circumscribed round to oval erythematous areas of depressed skin.^{1685,1686} In most cases, lesions are solitary, but more than one lesion is uncommonly present.¹⁶⁸⁷ There is a predilection for middle-aged and elderly females. A congenital case has been reported.¹⁶⁸⁸

Figure 9.39 Granular parakeratosis. This biopsy, from the axilla, shows a thick parakeratotic layer with retention of keratohyaline granules. (H&E)

The etiology is unknown. Chronic repetitive trauma may, in some cases, induce the lesions.¹⁶⁸⁹ HPV-4 has been isolated from one case¹⁶⁹⁰ and HPV-6 in another, but this latter patient had previously been treated for warts in the same location. HPV has been specifically excluded in other reports.^{1691,1692} It more likely represents a localized defect in keratinization on acral sites, morphologically expressed in the granular and horny layers.^{1692,1693} Kanitakis *et al.* reported actinic keratosis change in a lesion, possibly due to the increased susceptibility to photodamage resulting, at least in part, from the markedly reduced stratum corneum.¹⁶⁹⁴

Although the general impression has been that these lesions are asymptomatic and that no treatment is necessary,¹⁶⁹⁵ the development of precancerous change noted previously suggests that treatment may be indicated in certain circumstances, such as location in an area subjected to repetitive ultraviolet exposure. Cryotherapy¹⁶⁹⁶ has been used for this purpose.¹⁶⁹⁷ Photodynamic therapy¹⁶⁹⁸ and prolonged treatment with topical calcipotriol¹⁶⁹³ have also been effective in some cases.

Parenthetically, a case seen by the author more than 35 years ago was regarded by the late Dr. Hermann Pinkus, to whom the lesion was sent in consultation, as a 'minus nevus', a term with some merit.

Histopathology

The lesions show a broad zone of marked hypokeratosis contrasting with the adjacent normal volar skin. Many authors have described a 'sharp step' between the involved and uninvolved skin, but Resnik and DiLeonardo stated that in their cases the junction (interface) was angled in an irregular and frayed manner.¹⁶⁹⁹ The zone of hypokeratosis includes compact orthokeratin atop thin zones of parakeratosis of variable thickness.¹⁶⁹⁹ There is usually hypogranulosis beneath the parakeratosis. In the zone of hypokeratosis, acrosyringal corneocytes, when present, are compactly orthokeratotic and protrude slightly above the adjacent stratum corneum (Fig. 9.40).¹⁶⁹⁹ There is mild pallor of underlying keratinocytes and mild acanthosis. Dilated vessels are present in the papillary dermis and also rare inflammatory cells.

Figure 9.40 A circumscribed acral hypokeratosis. There is marked hypokeratosis with a 'sharp step' between involved and uninvolved skin. The hypokeratotic zone includes compact orthokeratin (parakeratosis is not evident in this example) and a granular cell layer of variable thickness atop an acanthotic epidermis. Note that acrosyringal corneocytes protrude above the adjacent stratum corneum. (H&E)

Electron microscopy

The corneocytes show intracytoplasmic splitting, but structures for cell attachment remain intact.¹⁶⁹¹

WHITE SPONGE NEVUS

Although white sponge nevus (OMIM 193900) predominantly affects noncornified stratified squamous epithelia, most often the buccal mucosa, it is considered here because pathogenic mutations in two of the keratin genes, *KRT4* and *KRT13*, have been found in this condition.¹⁷⁰⁰ *KRT4* maps to 12q13 and *KRT13* to 17q21–q22. These two keratins are normally found in the suprabasal keratinocytes of buccal, nasal, and esophageal mucosa, and anogenital epithelia.¹⁷⁰⁰

It is an autosomal dominant disorder characterized by thickened spongy mucosa with a white opalescent tint. It involves predominantly the buccal mucosa. It usually presents in early childhood. White sponge nevus has been reported in a patient with the ectrodactyly–ectodermal dysplasia–clefting syndrome.¹⁷⁰¹

Histopathology

The affected mucosa shows epithelial thickening, parakeratosis, and extensive vacuolization of the suprabasal keratinocytes.¹⁷⁰⁰

INTRODUCTION

This chapter deals with the various disorders of cutaneous pigmentation, excluding those entities in which there is an obvious lentiginous proliferation of melanocytes in sections stained with hematoxylin and eosin (H&E); it also excludes tumors of the nevus cell–melanocyte system. Both of the excluded categories are discussed in Chapter 32. Cutaneous pigmentation may also result from the deposition of drug complexes in the dermis. This category of pigmentation is discussed among other cutaneous deposits in Chapter 14. A related condition is the excessive dietary intake of carotenoid-containing foods, which may cause yellow-orange discoloration of the skin.^{1,2}

Cutaneous pigmentary disorders can be classified into two major categories: disorders with hypopigmentation and those with hyperpigmentation. The dyschromatoses, in which areas of both hypopigmentation and hyperpigmentation are present, have been arbitrarily included with the disorders of hyperpigmentation. A detailed list of all conditions resulting in discolorations of the skin was published in 2007.³

The pigmentary system

The pigmentary system involves a complex set of reactions with numerous potential sites for dysfunction.^{4,5} Melanin is produced in melanosomes in the cytoplasm of melanocytes by the action of tyrosinase on tyrosine. A number of intermediate steps involving the formation of dopa and dopaquinone occur prior to the synthesis of melanin. The melanin synthesized in any one melanocyte is then transferred to an average of 36 keratinocytes by the phagocytosis of the melanin-laden dendritic tips of the melanocytes.⁶ The protease-activated receptor 2 (PAR-2), which is expressed on keratinocytes, is a key receptor involved in melanosome transfer.⁷ Other important participants in this process include kinesin and actin-associated myosin V. The latter protein secures the peripheral melanosomes, preparing them for transfer to surrounding keratinocytes.⁸ This transfer of melanin can be disrupted by any inflammatory process involving the basal layer of the epidermis. Specific enzyme defects and destruction of melanocytes are other theoretical causes of hypopigmentation.

The pathogenesis of hyperpigmentation is not as well understood. Prominent pigment incontinence is an obvious cause of hyperpigmentation. Ultrastructural examination in some disorders of hyperpigmentation has shown an increase in size or melanization of the melanosomes, although in others the reasons for the basal hyperpigmentation have not been determined.

Skin color in the various races is an interesting topic, but it is beyond the scope of this book. A historical perspective was published in 2007.⁹ Another paper reviewed various aspects of racial and ethnic groups with pigmented skin, now called skin of color.¹⁰

The disorders of hypopigmentation are discussed first.

DISORDERS CHARACTERIZED BY HYPOPIGMENTATION

There are multiple potential sites for dysfunction in the formation of melanin pigment in basal melanocytes.⁶ Attempts have been made to categorize the various diseases with hypopigmentation on the basis of their presumed pathogenesis. The following categories may be considered:

1. *Abnormal migration/differentiation of melanoblasts*: piebaldism, Waardenburg's and Woolf's syndromes
2. *Destruction of melanocytes*: vitiligo, Vogt–Koyanagi–Harada syndrome, chemical leukoderma
3. *Reduced tyrosinase activity*: oculocutaneous albinism type 1A, phenylketonuria (?)
4. *Abnormal structure of melanosomes*: 'ash leaf spots' of tuberous sclerosis, Chédiak–Higashi syndrome, progressive macular hypomelanosis
5. *Reduced melanization and/or numbers of melanosomes*: albinism (other tyrosinase-positive variants), Griscelli syndrome, Elejalde syndrome, idiopathic guttate hypomelanosis, hypomelanosis of Ito, 'ash leaf spots', pityriasis versicolor (tinea versicolor), nevus depigmentosus
6. *Reduced transfer to keratinocytes*: nevus depigmentosus, pityriasis alba, postinflammatory leukoderma, pityriasis versicolor (tinea versicolor), Chédiak–Higashi syndrome. Increased degradation of melanosomes within melanocytes may also apply in some conditions listed in this section
7. *Abnormal vasculature*: nevus anemicus.

In addition to the conditions listed here, there are isolated reports of one or more cases in which the hypopigmentation does not correspond neatly to any of the named diseases.^{11–13} These cases are not considered further.

Phenylketonuria, an autosomal recessive disorder with a deficiency of the enzyme L-phenylalanine hydroxylase, is characterized by oculocutaneous pigmentary dilution in addition to neurological abnormalities.^{6,14} There are several steps in the biosynthesis of melanin that may be affected by this enzyme deficiency. Because biopsies are rarely taken, this condition is not discussed further.

PIEBALDISM

In piebaldism (partial albinism; OMIM 172800), an autosomal dominant disorder, there are nonprogressive, discrete patches of leukoderma present from birth.^{6,15} The chalk-white areas of hypomelanosis involve the anterior part of the trunk, the mid-region of the extremities, the forehead, and the mid-frontal area of the scalp beneath a white forelock.⁶ This hair change is present in up to 90% of those with piebaldism, and it is sometimes found as an isolated change in the absence of cutaneous leukoderma.¹⁶ Regression of the white forelock has also been reported.¹⁷ Within the areas of hypomelanosis are hyperpigmented and normally pigmented macules of various sizes.¹⁸

There are several rare syndromes in which extracutaneous manifestations accompany the piebaldism.^{6,15,19–21} Examples include the various types of Waardenburg's syndrome, in which piebaldism is associated with neurosensory hearing loss and other abnormalities including Hirschsprung's disease.^{22–28} Four major variants of Waardenburg's syndrome have been described, each one due to the involvement of different genes. The various types are listed in [Table 10.1](#). *PAX3*, the gene responsible for type I, regulates *MITF*, the gene responsible for type II. The *MITF* gene (microphthalmia-associated transcription factor) is assigned to chromosome 3p14.1–p12.3.²⁹ When type IV Waardenburg syndrome (OMIM 277580) is due to a mutation in the *SOX10* gene, it usually, but not always, is associated with Hirschsprung's disease.^{30,31} Neurofibromatosis 1 (NF-1) has also been associated with piebaldism.^{32–34} Although the coexistence of these two diseases is certainly possible, it has been noted that café-au-lait macules and axillary freckling can be features of piebaldism without coexistent neurofibromatosis.^{35,36} The explanation for this may be in the possible mechanistic relationship between piebaldism, associated with mutations of the *KIT* proto-oncogene (see later), and another, more recently described syndrome called Legius syndrome, an autosomal dominant disorder that features café-au-lait macules, axillary freckling, macrocephaly, and learning disabilities but lacks neurofibromas. Legius syndrome is caused by mutations in the *SPRED1* gene (Sprouty-related, Ena/vasodilator-stimulated phosphoprotein homology-1 domain-containing protein 1). The function of the *SPRED1* gene is to suppress the Ras/mitogen-activated protein kinase (MAPK) pathway, hyperactivity of which has been proposed to be involved in the pathogenesis

Table 10.1 Types of piebaldism and Waardenburg's syndrome

Disease	OMIM	Gene symbol	Gene locus	Comments
PBT	172800	<i>KIT</i> <i>SNA12</i>	4q11–q12 8q11	Two loci; white forelock, absence of pigment on forehead, chin, chest, abdomen, and extremities
WS type I	193500	<i>PAX3</i>	2q35	Above features + dystopia canthorum Cochlear deafness ± Hirschsprung's disease
WS type IIa	193510	<i>MITF</i>	3p14.1–p12.3	Pigmentary changes, absent dystopia canthorum (major difference from type I) May have hearing loss Hirschsprung's disease reported
WS type IIb	600193	?	1p21–p13.3	
WS type IIc	606662	?	8p23	
WS type IId	608890	<i>SLUG (SNA12)</i>	8q11	
WS type IIe	611584	<i>SOX10</i>	22q13	
WS type III (Klein–Waardenburg)	148820	<i>PAX3</i>	2q35	Is allelic to WS I or it involves a contiguous gene; upper limb abnormalities
WS type IV (Waardenburg–Shah)	277580	<i>EDNRB</i>	20q13.2–q13.3	Hirschsprung's disease; may involve endothelin-B receptor (<i>EDNRB</i>) or its ligand endothelin-3 (<i>EDN3</i>)
		<i>EDN3</i>	13q22	
		<i>SOX10</i>	22q13	

Note: Some of the associated abnormalities (e.g., Hirschsprung's disease) were described prior to accurate genetic knowledge. They may have been assigned to the wrong subgroup.
PBT, piebald trait; WS, Waardenburg's syndrome.

of café-au-lait macules. It has been postulated that, in piebaldism, loss of function of *SPRED1* due to inadequate phosphorylation of the *KIT*-binding domain by *KIT* may cause the development of these neurofibromatosis-like pigmented lesions.³⁶ Poliosis has also followed herpes zoster in the same dermatome; this may be an example of Wolf's isotopic response.³⁷

As mentioned previously, piebaldism results from mutations of the *KIT* proto-oncogene, which encodes a cell surface receptor, tyrosine kinase, whose ligand is the stem/mast cell growth factor.^{38,39} In humans, the *KIT* proto-oncogene has been mapped to the proximal long arm of chromosome 4 (4q11–q12).^{21,39,40} Some cases of piebaldism are caused by a mutation in the gene encoding the zinc finger transcription factor (*SNA12*) located on chromosome 8q11.⁴¹ Variations in the phenotype relate to the site of the *KIT* gene mutation. A novel *KIT* mutation, Val620Ala, results in piebaldism with progressive depigmentation.⁴² In mice, *KIT*-mediated signal transduction is required in embryogenesis for the proliferation and migration of melanoblasts from the neural crest. It appears to be required, in humans, for melanocyte proliferation.^{16,38,39} The successful use of autologous grafts to repigment the affected areas is not inconsistent with these theories.^{43,44} Noncultured epidermal cellular grafts are effective in restoring pigmentation, although it is difficult to obtain a perfect color match.⁴⁵

Histopathology

There are usually no melanocytes and no melanin in the leukodermic areas. Sometimes a small number of morphologically abnormal melanocytes are present, particularly near the margins of hypopigmentation. These melanocytes may have spherical melanosomes. Some clear cells, representing Langerhans cells, are usually present in the epidermis.⁴⁶

The hyperpigmented islands contain normal numbers of melanocytes: there are abundant melanosomes in the melanocytes and in keratinocytes. There are no dopa-positive melanocytes in the hair bulbs of the white forelock.²³

coalesce to form extensive areas of leukoderma.^{47–50} It results from selective destruction of melanocytes.⁵¹ An erythematous border is occasionally present in the initial stages.^{6,52–55} Repigmentation may lead to several shades of color in a particular lesion,⁵⁶ as may transitional stages in depigmentation (trichrome vitiligo).⁵⁷ The worldwide prevalence of vitiligo in the general population ranges between 0.5 and 2%;⁵⁸ the incidence in white people is approximately 1%,⁵⁹ but a study from China showed that this figure is an overestimation of its incidence.⁶⁰ Its first description dates back more than 3000 years.⁶¹ This condition may develop at any age, although in 50% or more of affected persons it appears before the age of 20 years.^{62–66} If there is an extended family history of vitiligo, onset is likely to be at an earlier age.⁶⁷ Late-onset vitiligo has been a neglected entity.⁶⁸ Almost 15% of late-onset cases demonstrate the Koebner phenomenon;⁶⁸ it may occur at any age.⁶⁹ A family history is present in up to 25% of cases; the inheritance appears to be polygenic.^{48,70–73} High-risk haplotypes have been identified in some groups;^{51,74} HLA-A2 is one of these.⁷⁵ The angiotensin-converting enzyme (*ACE*) gene has an association with the development of vitiligo.⁷⁶ Vitiligo does not appear to be caused by mutations in the GTP-cyclohydrolase I gene, which regulates melanin biosynthesis.⁷⁷

There is a predilection for the face, back of the hands, axillae, groins, umbilicus, and genitalia, and for the skin overlying bony areas such as the knees and elbows.⁴⁸ Vitiligo has been reported on the anterior neck in Muslim women.⁷⁸ It is thought to be due to the Koebner phenomenon resulting from the wearing of scarves that are tied with metallic or plastic pins in this region.⁷⁸ Periocular vitiligo commenced in one patient around a congenital divided nevus of the eyelid.⁷⁹ Sometimes the depigmented area is segmental or dermatomal in distribution (type B);⁶⁵ more often, it is more generalized (type A).^{80–82} Universal vitiligo in which the entire body is affected is rare.⁸³ Repigmentation seldom occurs in type B, which is also resistant to treatment and more common in children.^{81,84–86} Mucous membrane involvement with vitiligo involves primarily the lips and anogenital region. It can occur in three different settings: limited to mucosa, initial involvement of mucosa later spreading to the skin, and cutaneous vitiligo spreading to mucosa (the latter being the most common circumstance in one study).⁸⁷ Mucous membrane involvement may be associated with disease progression.⁸⁸

VITILIGO

Vitiligo (OMIM 193200) is an acquired, idiopathic disorder in which there are depigmented macules of variable size that enlarge and

Approximately 20–30% of individuals with vitiligo (usually those with bilateral/generalized disease)⁸⁴ have an associated autoimmune and/or endocrine disorder^{6,76,89,90} such as Hashimoto's disease,^{91,92} hyperthyroidism, pernicious anemia, Addison's disease,⁹³ insulin-dependent diabetes mellitus,^{94–96} and alopecia areata.^{64,97,98} In a series of 300 patients, there was a significantly higher prevalence of hypothyroidism and pernicious anemia among vitiligo patients.⁹⁹ Less frequent associations include various lymphoproliferative diseases,¹⁰⁰ morphea,¹⁰¹ chronic actinic dermatitis,¹⁰² urticaria,⁶⁵ pemphigus vulgaris,¹⁰³ the mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes syndrome (MELAS),¹⁰⁴ Crohn's disease,^{105,106} autoimmune polyglandular syndrome,^{107,108} prior infection with cytomegalovirus,^{109–111} HIV infection,¹¹² idiopathic CD4⁺ T-cell lymphocytopenia,¹¹³ and chronic mucocutaneous candidosis.¹¹⁴ The reported association of vitiligo with psoriasis and erythema dyschromicum perstans¹¹⁵ is probably fortuitous.¹¹⁶ Depigmentation resembling vitiligo has been reported following contact with hydroquinones, certain phenolic agents,⁴⁸ cinnamic aldehyde in toothpaste,¹¹⁷ topical minoxidil,¹¹⁸ flutamide,¹¹⁹ chloroquine,¹²⁰ imiquimod,^{121–123} tazarotene,¹²⁴ adalimumab,¹²⁵ diphenylcyclopropenone,¹²⁶ dasatinib,¹²⁷ and PUVA therapy.^{128–130} Infliximab therapy has been associated with worsening of vitiligo and new onset of a psoriasiform dermatitis¹³¹ and also with development of vitiligo in a patient treated for ulcerative colitis.¹³² Ganciclovir, used in the treatment of graft-versus-host disease (GVHD), produced extensive vitiligo in one patient.¹³³ Vitiligo has also followed the use of interferon- α (IFN- α) therapy for hepatitis B infection.¹³⁴ It has also occurred at the site of IFN- α 2b injection in a patient with chronic viral hepatitis C¹³⁵ and in two patients receiving pegylated IFN- α 2a for chronic hepatitis C.¹³⁶ Capecitabine has produced hyperpigmentation in nonvitiliginous skin in a patient with cancer treated with this drug.¹³⁷ Many cases of depigmentation, some resembling vitiligo, have been reported following the use of the tyrosine kinase inhibitor imatinib, which is used in the treatment of chronic myeloid leukemia.^{138–141}

Vitiligo has developed after initiation of antiretroviral treatment with zidovudine, lamivudine, and efavirenz and then resolved during that therapy – a possible example of the immune reconstitution inflammatory syndrome.¹⁴² Vitiligo may be accompanied by a variety of ocular pigmentary disturbances.¹⁴³ The best known of these is the Vogt-Koyanagi-Harada syndrome, which includes uveitis, poliosis, dysacusis, alopecia,¹⁴⁴ vitiligo, and signs of meningeal irritation.^{145,146} Not all these features are present in all cases. An immunological etiology has been suggested.¹⁴⁷ A rare variant of this syndrome with inflammatory vitiligo has been described.¹⁴⁸

Sometimes there is a history in the patient or the patient's immediate family of premature graying of the hair (poliosis), a halo nevus, or even a malignant melanoma.^{82,149} Vitiligo may be a presenting sign of metastatic melanoma.¹⁵⁰ It is interesting to note that individuals with metastatic melanoma who develop vitiligo-like depigmentation have a better prognosis than those who do not.^{151,152} Both lesions have clonally expanded T cells with identical BV (β variable) regions.¹⁵³

Vitiliginous skin is generally resistant to developing dermatitis in response to contact allergens, and it also has the remarkable property of resistance to forming nonmelanoma skin cancers, in contrast to the depigmented skin of albinos.¹⁵⁴

The onset of vitiligo is usually insidious with no precipitating cause. In approximately 20% of cases, it develops after severe sunburn or some severe emotional or physical stress.^{48,91} The majority of cases have a progressive clinical course.^{155,156} In generalized forms (vitiligo vulgaris), the depigmentation may eventually involve large areas of skin. Some repigmentation may occur, but it is usually incomplete and short lived.^{48,145} Repigmentation probably involves melanocytes from hair follicles (*perifollicular repigmentation*).^{157,158} It may also occur from melanocytes in adjacent normal skin (*marginal repigmentation*) and possibly from dopa-negative melanocytes in vitiliginous skin that have been hypothesized to give *diffuse repigmentation*.¹⁵⁹ Marginal and

perifollicular repigmentation are more stable than the diffuse form, which tends to result when steroid therapy is used.¹⁵⁹ Eventually, the process of depigmentation ceases. The evolution and therapeutic monitoring of vitiligo can be carried out using *in vivo* reflectance confocal microscopy.⁵⁹ Vitiligo may have a significant effect on the psychological well-being of some patients,¹⁶⁰ particularly dark-skinned persons, in whom the lesions may be confused with leprosy, resulting in social stigmatization.^{66,161}

Pathogenesis

Several hypotheses have been proposed to explain the destruction of melanocytes that results in the depigmentation.^{50,145,162,163} These may be summarized as the neural, the self-destructive, the inherent defect, and the autoimmune theories.¹⁶⁴ They are not mutually exclusive.^{93,165} One study provides evidence for a link between the neural and apoptotic pathways in the pathogenesis of the disease.¹⁶⁶ The neural hypothesis suggests that a neurochemical mediator released at nerve endings results in destruction of melanocytes. It has been proposed that the segmental form (type B) of vitiligo results from dysfunction of sympathetic nerves in the affected areas.⁸¹ Support for this hypothesis comes from the finding of increased neuropeptide Y activity in vitiligo.¹⁶⁷ The self-destruction hypothesis (autocytotoxicity) is based on the known toxicity of melanin precursors for melanocytes. It is assumed that affected individuals have an intrinsic inability to eliminate or handle these toxic precursors, such as free radicals, which accumulate and result in the destruction of melanocytes by apoptosis.^{49,168} More recent studies have confirmed that oxidative stress is involved in the pathophysiology of vitiligo.^{169,170} Whether such mechanisms are involved in producing the DNA damage observed in patients with vitiligo is unknown.¹⁷¹ Experimental studies suggest that early cell death of vitiligo melanocytes is related to their increased sensitivity to oxidative stress, which may in some way be linked to the abnormal expression of tyrosinase-related protein (TRP-1).¹⁷² The autoimmune hypothesis, which is currently most favored, particularly for the generalized forms, proposes that antibody-dependent, cell-mediated cytotoxicity utilizing natural killer cells is responsible for the loss of melanocytes.^{173,174} Based on an association with other autoimmune skin diseases, one group of authors has proposed a three-step process in the development of segmental vitiligo that would involve a combination of oxidative stress and autoimmune phenomena: release of inflammatory cytokines, increased antigen presentation or formation of neoantigens due to oxidative stress, and intranodal proliferation of activated, melanocyte-specific T cells with migration to the skin.¹⁷⁵ Type 1 cytokines have been incriminated in this process.¹⁷⁶ Infiltrating T cells and macrophages have been observed adjacent to the remaining perilesional melanocytes in generalized vitiligo.¹⁷⁷ However, other studies have suggested that antibodies to melanocytes in the IgG fraction of patients' serum may be the effector mechanism for melanocyte destruction;^{89,178–181} the level of the antibodies correlates with disease activity.¹⁸² The antibodies appear to be directed against tyrosinase in some patients, despite earlier reports to the contrary.^{183–186} At least 15 different antigens may be recognized in some individuals with vitiligo by vitiligo autoantibodies.⁸⁹ Other experiments also downplay the role of natural killer and lymphokine-activated killer cells in the pathogenesis.^{187–189} Various other abnormalities in the immune system have been recorded in vitiligo.¹⁹⁰ These include a decrease in T-helper cells,^{191–193} an increase in natural killer cells,^{192,194} circulating antibodies to surface antigens on melanocytes^{195–198} and to certain melanoma cell lines,^{199,200} aberrant expression of complement regulatory proteins,²⁰¹ an increase in met-enkephalin secretion,²⁰² a decrease in the expression of c-kit protein by melanocytes adjacent to lesional skin,^{203,204} abnormal expression of MHC class II molecules and ICAM-1 by perilesional melanocytes,²⁰⁵ possible functional impairment of Langerhans cells,^{206,207} elevated serum and tissue levels of interleukin (IL)-17,²⁰⁸ altered levels

Figure 10.1 Vitiligo. (A) Melanocytes and melanin are absent from the basal layer. (H&E) (B) No melanin can be seen in the basal layer or dermis in this stain for melanin. (Masson-Fontana)

of the nuclear receptor protein LXR- α ,²⁰⁹ and abnormal number and/or function of regulatory T cells (Tregs) and the potential effects on tolerance to melanocyte self-antigens.²¹⁰ In melanoma-associated vitiligo, CD8⁺ T cells are important in the pathogenesis.²¹¹

Vitiligo has developed in a patient after bone marrow transplantation from a donor with vitiligo.²¹² It has also developed in two patients who were given a donor lymphocyte infusion for leukemia relapse more than 3 years after bone marrow transplantation.²¹³

Work has associated the cytotoxic T lymphocyte antigen-4 (CTLA-4) gene product, which is involved in controlling T-cell apoptosis, with susceptibility to autoimmune diseases including vitiligo. It is important to note that significant associations of vitiligo with *CTLA-4* polymorphic markers are only seen in patients with concomitant autoimmune diseases, suggesting there may be two forms of vitiligo.⁸⁹ A recent paper concluded that *CTLA-4* was not associated with a risk of generalized vitiligo, but that polymorphisms in the *PTPN22* gene were.²¹⁴ Polymorphisms in the autoimmune regulator gene (*AIRE*) are sometimes found in patients with vitiligo.²¹⁵

Treatment options for localized disease include topical calcineurin inhibitors, phototherapy, and transplantation with autologous melanocytes or epidermal cell suspensions (see later).^{216–225} When larger areas of the body are involved (body surface area (BSA) 11–80%), phototherapy with or without antioxidants is the treatment of choice.^{225–228} Other options include autologous minigrafting^{219,229–234} or, if more than 80% of the BSA is involved, depigmentation of normal skin with a hydroquinone cream or a combination of the cream with Q-switched ruby laser therapy.^{225,235} Other topical agents include moderate- to high-potency topical corticosteroids,²³⁶ tacrolimus ointment²³⁷ (although rapid enlargement of a malignant melanoma occurred in a child with vitiligo after the application of topical tacrolimus²³⁸), pimecrolimus cream,²³⁹ tacalcitol cream and sunlight exposure,²⁴⁰ tanning preparations, topical dyes, tattooing,²²⁵ and camouflaging of vitiligo with 6% dihydroxyacetone cream,²⁴¹ Dermablend®, or Covermark®.²⁴¹ Other approaches have included low-dose, narrowband, ultraviolet B (UVB)-activated pseudocatalase PC-KUS to remove/reduce H₂O₂ levels in vitiligo,²⁴² proton pump inhibitors (however, vitiligo has been precipitated by these drugs²⁴³), and efalizumab therapy when given for psoriasis.²⁴⁴ Phototherapy approaches include narrowband ultraviolet-B radiation (NB-UVB),^{226–228,245–247} 308-nm monochromatic excimer light,^{248–250} or combinations of NB-UVB phototherapy with supplemental antioxidants such as α -lipoic acid or oral *Polypodium leucotomos*.^{251,252} With phototherapy, a perifollicular pattern of repigmentation is the predominant one; it is the most stable pattern of repigmentation.¹⁵⁹

Figure 10.2 Vitiligo. A melanocyte with a giant melanosome is present at the edge of the depigmented area. (H&E)

PUVA keratoses have developed in vitiligo skin treated with PUVA therapy.²⁵³ Surgical procedures^{254,255} include the use of noncultured autologous melanocyte or epidermal cell suspensions,^{256–258} transplantation of autologous melanocytes cultured on amniotic membrane²⁵⁹ or in fibrin suspension,^{260,261} autologous minigrafting, and suction blister epidermal grafting.^{262,263}

Histopathology

As a general rule, vitiliginous skin shows a complete loss of melanin pigment from the epidermis and an absence of melanocytes (Fig. 10.1). At the advancing border, the melanocytes may be increased in size with an increased number of dendrites (Fig. 10.2).⁴⁸ Occasional lymphocytes may be present in this region;²⁶⁴ these cells are invariably present if there is an inflammatory border clinically.²⁶⁵ Sometimes these epidermotropic lymphocytes form small Pautrier-like collections in the basal layer.²⁶⁶ In these instances, there is also a perivascular infiltrate of mononuclear cells involving the superficial plexus, as well as some superficial edema.²⁶⁷ A heavy lymphocytic infiltrate in the upper dermis is a rare finding.²⁶⁸ In a study of 210 cases of vitiligo, marginally active lesions with erythema, scaling, and hyperpigmentation were identified in 13% of cases. Lymphocytic infiltration of the

Figure 10.3 Vitiligo. A lymphocyte is present next to a melanocyte showing early apoptosis. Melanocytes are absent elsewhere in the basal layer. (H&E)

dermoepidermal interface was observed in 89% of these cases.²⁶⁹ Focal spongiosis is sometimes present in the marginal areas of vitiligo.²⁶⁶ Ultrathin sections will often show vacuolated keratinocytes and extracellular granular material in the basal layer of the normal skin adjacent to areas of vitiligo.²⁷⁰ If serial sections are examined, a lymphocyte will sometimes be found in close apposition to a melanocyte at the advancing edge (**Fig. 10.3**).²⁶⁶ Degenerative changes have also been reported in nerves and sweat glands.²⁷¹ Merkel cells were absent from lesional skin in one study.²⁷² Langerhans cells are usually increased.²⁷³ For this reason, it is the author's practice to perform a melan-A and HMB-45 stain on all suspected cases of vitiligo; this allows the proper assessment of melanocyte numbers. Molecular studies have found that some lesions of vitiligo show focal melanocyte survival.²⁷⁴ This has been confirmed by a histopathological study of 100 cases of vitiligo. In 12 of the cases, some melanocytes were present. In 16% of cases, there was some melanin in the basal layer with the Masson-Fontana stain.²⁷⁵ Other changes that have been reported include suprabasilar vacuolization, a thinned epidermis or effacement of the dermal-epidermal junction, and degeneration of a number of structures including appendages and dermal nerves.^{271,276} Melanocytes are always reduced more in vitiligo than they are in nevus depigmentosus.²⁷⁵

The incidence of actinic damage and various skin cancers is surprisingly low in vitiligo patients, possibly because they practice sun-protection strategies.²⁷⁷

Experimentally, if minor trauma is applied to nonlesional vitiligo skin, melanocytes become detached and undergo transepidermal elimination.²⁷⁸ This may be the mechanism of the depigmentation occurring in the Koebner phenomenon.²⁷⁸

Electron microscopy

Melanocytes are absent from lesions of long standing.²⁷⁹ Melanocytes and keratinocytes adjacent to the vitiliginous areas show degenerative changes in the form of intracellular edema and vacuolar formation.^{270,279-281} Extracellular material derived from degenerating keratinocytes is sometimes present.²⁷⁰ Fibrillar masses similar to colloid bodies may also be present in the upper dermis and in the basal layer.²⁷⁰ Similar changes are seen in stable vitiligo, indicating ongoing damage to keratinocytes, melanocytes, and Langerhans cells resembling, in part, the changes seen in the lichenoid reaction.²⁸² Numerous nerve endings may be seen in close contact with the basal lamina.²⁸⁰ There may be increased thickness of the basement membrane of Schwann cells and features of both axonal degeneration and nerve regeneration.²⁸³

Differential diagnosis

Biopsies of depigmented areas showing only an absence of melanocytes are difficult to distinguish from either chemical depigmentation or piebaldism without additional clinical information. However, sampling of a lesion that includes the lesional border might show mild melanocyte enlargement, spongiosis, or interface changes – features that would be more in keeping with vitiligo. Depigmentation accompanying certain inflammatory diseases, such as discoid lupus erythematosus, may also show characteristic epidermal, appendageal, or inflammatory changes, whereas scarring in a depigmented area suggests the effects of either a prior inflammatory process or trauma, such as a burn or radiation injury.

OCULOCUTANEOUS ALBINISM

Oculocutaneous albinism is a genetically heterogeneous group of disorders in which there is a generalized decrease or absence of melanin pigment in the eyes, hair, and skin.^{284,285} At least 10 forms of this condition have been identified, each presumably resulting from a different biochemical block in the synthesis of melanin (**Table 10.2**).⁶ The most common forms are types 1 and 2, which account for 40 and 50%, respectively, of cases worldwide.²⁸⁶ Ocular albinism, in which the pigmentary deficit is confined to the eyes, is not considered.²⁸⁷

Type 1A oculocutaneous albinism (OCA1A)

In type 1A, the classic type (OMIM 203100), the defect is a complete absence of tyrosinase activity in melanocytes.²⁸⁸ The tyrosinase gene (*TYR*) has been cloned. It is present on chromosome 11q14–q21.²⁸⁹⁻²⁹¹ Many different mutations of type 1A have been described.^{289,292,293} Prenatal diagnosis of type 1A can be made by performing a dopa test on the hair bulbs of fetuses, obtained by scalp biopsy.²⁹⁴ This technique has been superseded by analysis of the fetal tyrosinase gene.²⁹⁵ Inheritance is autosomal recessive in type. The clinical presentation at birth is white hair and skin and blue eyes.

Ocular disorders include photophobia, nystagmus, strabismus, and reduced visual acuity. In the skin, there is accelerated photoaging and an increased incidence of keratoses and squamous and basal cell carcinomas.^{296,297} Malignant melanomas develop occasionally.²⁹⁸ The dysplastic nevus syndrome has also been reported in individuals with

Table 10.2 Types of oculocutaneous albinism

Type	OMIM	Gene symbol	Gene name	Gene locus	Comments
OCA1A	203100	<i>TYR</i>	Tyrosinase	11q14–q21	Complete absence of tyrosinase activity in melanocytes
OCA1B	606952	<i>TYR</i>	Tyrosinase	11q14–q21	Reduced activity of tyrosinase; splicing mutation described
OCA2	203200	<i>P (OCA2)</i>	Pink-eyed dilution	15q11–q13	<i>P</i> gene also deleted in cases of Prader–Willi and Angelman syndrome; variant in Africa with palmoplantar freckles
OCA3	203290	<i>TYRP1</i>	Tyrosinase-related protein 1	9p23	Found predominantly in Africans
OCA4	606574	<i>MATP (SLC45A2)</i>	Membrane-associated transporter protein	5p13.3	Common in Japan

Hermansky–Pudlak syndrome and Chédiak–Higashi syndrome are other variants.

oculocutaneous albinism.²⁹⁹ Lentigines and nevi do not form in type 1A, the tyrosinase-negative phenotype.⁶

In all phenotypes except type 1A, there is some increase in pigment with age, with the amount depending on the ethnic background of the individual and the particular subtype of the disorder.²⁸⁴ Red-yellow pheomelanin is the first to form; black-brown eumelanin is synthesized only after a long period of pheomelanin formation.²⁸⁴

Yellow mutant oculocutaneous albinism (type 1B; OCA1B)

In yellow mutant oculocutaneous albinism (type 1B; OMIM 606952), tyrosinase activity and melanin biosynthesis are greatly reduced.²⁹³ There is extreme hypopigmentation at birth, with the eventual development of yellow or blond hair. A splicing mutation of the tyrosinase gene (*TYR*) on chromosome 11q14–q21 has been reported.³⁰⁰

Oculocutaneous albinism type 2 (OCA2)

In oculocutaneous albinism type 2 (OMIM 203200), an autosomal recessive disease, there is defective melanin production in the skin, hair, and eyes.³⁰¹ It is caused by mutations of the *P* gene (*OCA2*), located on chromosome 15q11–q13 and thought to act as a transporter in the melanosomal membrane.³⁰² The *P* gene is deleted in the majority of patients with Angelman syndrome (OMIM 105830) and Prader–Willi syndrome (OMIM 176270).³⁰¹ This variant (*OCA2*) is common in some areas of Africa; in Tanzania, its incidence is 1 in 1400 people per year.³⁰³ Skin cancer is a problem in some of these individuals.³⁰³

Tyrosinase-positive oculocutaneous albinism (OCA2 variant)

In tyrosinase-positive oculocutaneous albinism, one of the most common genetic conditions in Africa, there is also a defect in chromosome 15q11–q13. It appears to be a phenotypic variant of type 2. Palmoplantar freckles and melanocytic nevi occur in a significant number of subjects with this form of the disease.³⁰⁴

Oculocutaneous albinism type 3 (OCA3)

This variant (OMIM 203290) is caused by mutations in the tyrosinase-related protein-1 (*TYRP1*) gene located at 9p23. It is found predominantly in Africans, although it has been reported in a consanguineous Pakistani family.²⁸⁶ The so-called rufous variant (OMIM 278400), which occurs in black individuals, is characterized by bright copper-red coloration of the skin and hair and dilution of the color of the iris.²⁸⁶ It is also due to a mutation in the *TYRP1* gene.

Oculocutaneous albinism type 4 (OCA4)

This variant (OMIM 606574) is due to mutations in the membrane-associated transporter protein (*MATP*, *SLC45A2*) gene on chromosome 5p13.3.^{305,306} It has been suggested that *OCA4* is one of the most common types of albinism in Japan.³⁰⁷

Hermansky–Pudlak syndrome

The Hermansky–Pudlak syndrome (OMIM 203300) is a rare, autosomal recessive disorder of lysosome-related organelle biosynthesis resulting in melanosome dysfunction and absent platelet-dense bodies.³⁰⁸ Eight subtypes of Hermansky–Pudlak syndrome (HPS) have been identified (HPS-1 through HPS-8); all exhibit oculocutaneous albinism and absent platelet-dense bodies.^{308,309} Additional features are present in each subtype, which may include pulmonary fibrosis and immunodeficiency. Several subtypes are limited to single case reports. Lipid and ceroid pigment are present in macrophages in various organs, including the skin.³¹⁰ Pulmonary ceroid deposition leading to respiratory failure is a common cause of death in HPS-1 and HPS-4.^{308,311} Nine causative genes have been identified to date.³¹² The *HPS-1* gene, mutations of which are responsible for the Hermansky–Pudlak syndrome type 1, maps to chromosome 10q23.^{313,314} Mutations cause lysosomal dysfunction in platelets and melanocytes, possibly by affecting calcium channel integrity in the cells.^{315,316} Other cutaneous findings, most often related to a specific 16-base pair duplication of the *HPS1* gene, include dysplastic nevi, acanthosis nigricans-like lesions in the neck and axilla, and trichomegaly.³¹³ There is a suggestion that a patient with HPS-1 may be predisposed to the development of systemic lupus erythematosus.³¹⁷ Metastatic cutaneous involvement of granulomatous colitis has been reported in a child with HPS.³¹⁸

Hermansky–Pudlak syndrome type 2 (OMIM 608233), the only other subtype that is considered here, is caused by a mutation in the gene encoding the β -3A subunit of the AP3 complex (*AP3B1*). It includes immunodeficiency in its phenotype, and patients have an increased susceptibility to infections as a consequence of neutropenia. The gene maps to 5q14.1.

The Chédiak–Higashi syndrome, the Griscelli syndrome, and the Elejalde syndrome (see later) are sometimes regarded as other clinical variants of oculocutaneous albinism. They have in common the presence of silvery hair and mild skin coloration that is not strictly albinism.

Generalized cutaneous depigmentation resembling albinism has been reported in a patient treated with a sulfonamide. However, the absence of melanocytes on electron microscopy was more in keeping with vitiligo or chemical leukoderma.³¹⁹

Figure 10.4 Albinism. Melanin is absent from the basal layer, but melanocytes are normal in number and morphology. (H&E)

Histopathology

There is a complete or partial reduction in melanin pigment in the skin and hair bulbs. Melanocytes are normal in number and morphology (Figs. 10.4 and 10.5). Tyrosinase activity is lacking in melanocytes in freshly plucked anagen hair bulbs in type 1A;³²⁰ it is reduced in heterozygotes with this phenotype and variably reduced in some of the other types. Tyrosinase activity is normal in type 2.²⁸⁸ The lesion of cutaneous ‘metastatic’ granulomatous colitis in a patient with HPS showed a dermal infiltrate, located adjacent to an ulcer, composed of non-necrotizing granulomas, histiocytes, and lymphocytes.³¹⁸

Electron microscopy

Melanocytes and melanosomes are normal in configuration. There are no stage III or IV melanosomes in type 1A. Macromelanosomes have been found in the basal layers of the epidermis in HPS.^{316,321} The melanocytes have shortened dendritic processes.³²²

CHÉDIAK–HIGASHI SYNDROME

The Chédiak–Higashi syndrome (OMIM 214500) is a rare, autosomal recessive disorder in which there is partial oculocutaneous albinism associated with frequent pyogenic infections and the presence of abnormal, large granules in leukocytes and some other cells.^{323–326} HPS (discussed previously) is a similar but distinct entity. The disease usually enters an accelerated phase in childhood, with pancytopenia, hepatosplenomegaly, and lymphohistiocytic infiltrates in various organs.³²⁷ This phase, which resembles the virus-associated hemophagocytic syndrome, is usually followed by death.³²⁷

The pigmentary dilution involves at least one and often all three of the following: skin, hair, and eyes.^{323,328} There is increased susceptibility to burning. The hair is usually blond or light brown in color. Speckled hypopigmentation and hyperpigmentation of sun-exposed areas is sometimes found in darkly pigmented races.^{329,330}

The increased susceptibility to infection is related to impaired function of leukocytes and natural killer cells associated with lysosomal defects, whereas the reduced skin pigmentation is related to similar defects in melanocytes.^{327,331} The inclusions found in these and other cells are massive secondary lysosomal structures formed through a combined process of fusion, cytoplasmic injury, and phagocytosis.^{327,331}

The gene responsible for this condition maps to chromosome 1q42.1–q42.2. The gene has been designated *LYST* (lysosomal

Figure 10.5 Albinism. This biopsy was obtained from a patient with tyrosinase-positive oculocutaneous albinism. (A) Again, melanin is absent from the basal layer. (H&E) (B) Immunohistochemical staining for tyrosinase, showing scattered, positively staining melanocytes along the junctional zone.

trafficking regulator). Unrelated cord blood transplantation has shown promise in treating some individuals without HLA-matched donors, correcting the hematologic and immunologic defects in these patients.³³²

Histopathology

There is a striking reduction or even absence of melanin pigment in the basal layer and in hair follicles.³²³ A few large pigment granules corresponding to giant melanosomes are present.³³³ In less affected individuals and in some heterozygotes, clumps of enlarged pigment granules may also be present in the dermis in macrophages and endothelial cells and lying free in the interstitium.³²⁸

Staining with toluidine blue demonstrates large cytoplasmic inclusions in cutaneous mast cells.³³³

Electron microscopy

Giant melanosomes and degenerating cytoplasmic residues are found in melanocytes.³³⁴ The pigment granules passed to keratinocytes are larger than normal.³³⁴ The giant melanosomes appear to arise from

defective premelanosomes.³³⁴ Giant cytoplasmic granules have also been found in Langerhans cells.³³⁵ They are believed to be derived from the fusion of lysosomes or some portion of Birbeck granules.³³⁵ Electron microscopy has also been used to rapidly detect the success of bone marrow transplantation in Chédiak–Higashi patients by finding dense bodies (serotonin-containing storage organelles) in their platelets.³³⁶

GRISCELLI SYNDROME

The Griscelli syndrome is characterized by reduced skin pigmentation, often regarded as partial albinism, and silvery-gray hair combined in one type with immunodeficiency.^{337,338} Three types have been described: type 1 (OMIM 214450), caused by mutations in the myosin VA gene (*MYO5A*) at chromosome 15q21 and without immunological impairment; type 2 (OMIM 607624), caused by mutations in the *RAB27A* gene at 15q21, the same location as the *MYO5A* gene, and with immunological impairment³³⁹ accompanied by a hemophagocytic syndrome;³⁴⁰ and type 3 (OMIM 609227), characterized by hypomelanosis with no immunological or neurological changes and caused by mutations in the melanophilin (*MLPH*) gene at 2q37 or the *MYO5A* gene.³⁴¹ There are no abnormal cytoplasmic granules in leukocytes as found in Chédiak–Higashi syndrome (discussed previously). Type 2 Griscelli syndrome has been associated with lymphomatoid granulomatosis, an Epstein–Barr virus-related lymphoproliferative disorder.³⁴⁰

Histopathology

Enlarged hyperpigmented basal melanocytes with sparsely pigmented adjacent keratinocytes are seen on skin biopsy specimens.³⁴² Pigment clumps can be observed within the hair shafts of these patients.³⁴³

Laser scanning confocal microscopy in patients with type 3 Griscelli syndrome shows perinuclear aggregation of melanosomes within melanocytes.³⁴³

Electron microscopy

There are some type IV melanosomes in basal melanocytes and shortened dendritic processes. The hair shafts show uneven clusters of aggregated melanin pigment, mainly in the medulla.³³⁷

ELEJALDE SYNDROME

The Elejalde syndrome (acrocephalopolydactylous dysplasia; OMIM 256710) is a rare autosomal recessive disorder characterized by the triad of silvery hair, hypopigmented skin (sometimes referred to as partial albinism) and severe dysfunction of the central nervous system (hypotonia, seizures, and mental retardation).³⁴⁴ Thickened skin has also been reported.³⁴⁵ It has also been called neuroectodermal melanolysosomal disease.³⁴⁶ There is no immunodeficiency as seen in type 2 Griscelli syndrome or Chédiak–Higashi syndrome, which share clinical features with Elejalde syndrome. It has been proposed that Elejalde syndrome and Griscelli syndrome type 1 (OMIM 214450) may represent the same entity.³⁴⁷ If so, it is caused by a mutation in the gene encoding myosin VA (*MYO5A*), which maps to chromosome 15q21.

Histopathology

Melanin granules in the basal layer are of irregular size and distribution with overall reduced pigmentation. Hair shafts are similar to those seen in Griscelli syndrome (discussed previously). An autopsy performed on a stillborn baby with the syndrome showed “dermal collagenization” and subcutaneous edema.³⁴⁵

PROGRESSIVE MACULAR HYPOMELANOSIS

Progressive macular hypomelanosis of the trunk is an acquired form of hypopigmentation with a predisposition to affect the back of young adult females of Caribbean origin.³⁴⁸ It has also been reported from other countries, including Singapore.³⁴⁹ The hypopigmented macules, which measure 1–3 cm in diameter, coalesce into large patches. The disease is often misdiagnosed as tinea (pityriasis) versicolor.³⁵⁰ The disease may remit after 3 or 4 years. One study suggested that idiopathic guttate hypomelanosis (see later) is a related disorder along a spectrum of disorders of depigmentation.³⁵¹ Extensive pityriasis alba was thought to be the same condition,³⁵² but this theory has since been rejected.³⁵³ On the basis of red follicular fluorescence in hypopigmented spots, and culture results, it has been proposed that progressive macular hypomelanosis may result from *Propionibacterium acnes*.^{354,355} A study using culture and quantitative real-time polymerase chain reaction (PCR) technology showed a predominance of *P. acnes* in lesional skin compared to nonlesional skin.³⁵⁶ Antiretroviral therapy has also been suspected of being a cause in at least one case.³⁵⁷

The disease does not always respond to conventional treatment including PUVA; treatment with this modality has been effective but does not appear to prevent recurrence.³⁵⁸ A number of cases have been successfully treated with narrowband UVB.^{357,359–361} In a randomized study, antimicrobial therapy in conjunction with light (benzoyl peroxide/clindamycin/UVA) was more effective than a combination of anti-inflammatory therapy and light (fluticasone/UVA).³⁵⁵ The effectiveness of topical clindamycin, alone or in combination with benzoyl peroxide, has been confirmed in a number of studies.³⁶² Improvement occurred in a reported case with sunlight exposure and doxycycline.³⁵⁰

Histopathology³⁴⁸

Routine light microscopic findings are minimal. A few lymphocytes can be found in the superficial dermis. There is a decrease in melanin pigment within the epidermis.³⁶³ Using S-100 protein, TRP-1, and antihuman tyrosinase (T311) staining, melanocytes are normal in number compared to surrounding uninvolved skin.³⁶³

Electron microscopy

There is a reduction in stage IV (negroid) melanosomes, which are replaced by small type I–III melanosomes in an aggregated (caucasoid) pattern. This results in a decrease of epidermal melanin.³⁶⁴

TUBEROUS SCLEROSIS ('ASH LEAF SPOTS')

Tuberous sclerosis (OMIM 191100) is characterized by the triad of epilepsy, mental retardation, and multiple angiofibromas ('adenoma sebaceum') (see p. 968). In addition, circumscribed macules of hypopigmentation known as 'ash leaf spots' can be present at birth on the trunk and lower extremities.^{6,365} They vary in diameter from 1 mm to 12 cm. The more common shapes are oval, polygonal, or ash leaf-like. The basic abnormality appears to be an arrest in the maturation of melanosomes.⁶ Tuberous sclerosis exhibits genetic heterogeneity. This entity is discussed further in Chapter 34, page 968.

Histopathology

Epidermal melanin is reduced but not absent (Fig. 10.6).

Electron microscopy^{6,366}

Electron microscopy has shown a normal number of melanocytes and a reduction in the number, size, and melanization of the melanosomes.³⁶⁵ The small melanosomes often form aggregates within the keratinocytes.

Figure 10.6 Ash leaf macule of tuberous sclerosis. Epidermal melanin is reduced compared to the patient's adjacent normal skin. (H&E)

Figure 10.7 Idiopathic guttate hypomelanosis. The changes are on the left side of the figure. Note the basket-weave stratum corneum and the decrease in epidermal melanin. The epidermis is not atrophic in this example. (H&E)

IDIOPATHIC GUTTATE HYPOMELANOSIS

Idiopathic guttate hypomelanosis is a common leukodermic dermatosis of unknown etiology in which multiple achromic or hypochromic macules, 2–5 mm in diameter, develop over many years.^{367–370} They are usually found on the sun-exposed extremities of elderly individuals, but scattered lesions may occur on the trunk.^{371–373} Repigmentation does not occur. A likely hyperkeratotic variant has been described.³⁷⁴ The author and colleagues have seen this pattern of pigmentation in patients who have received bone marrow transplants (unpublished observation). In a group of renal transplant patients, the presence of this condition correlated with the presence of HLA-DQ3.³⁷⁵ Therapies that have been successfully employed in inducing repigmentation in these lesions include topical calcineurin inhibitors³⁷⁶ and the use of fractional carbon dioxide lasers.³⁷⁷

Histopathology^{369,370,378}

There is a decrease in melanin pigment in the basal layer of the epidermis and a reduction in the number of dopa-positive melanocytes, although these cells are never completely absent. The epidermis usually shows some atrophy (more pronounced in non-sun-exposed sites), with flattening of the rete pegs. There may be basket-weave hyperkeratosis, but compact hyperkeratosis has also been described (Fig. 10.7).³⁷⁹

Electron microscopy

Some of the melanocytes remaining in affected areas of skin show a reduction in dendritic processes and melanosomes.^{380,381} Dilated endoplasmic reticulum and mitochondrial swelling have also been identified, suggestive of melanocyte degeneration.³⁷⁹

HYPOMELANOSIS OF ITO

Hypomelanosis of Ito (incontinentia pigmenti achromians; OMIM 300337) presents at birth or in infancy with sharply demarcated, hypopigmented macular lesions on the trunk and extremities, with a distinctive linear or whorled pattern distributed along the lines of Blaschko.^{382–387} The pattern resembles a negative image of the pigmentation seen in incontinentia pigmenti (see p. 340).³⁸⁸ The coexistence

of hypomelanosis of Ito and incontinentia pigmenti in the same family, even though disputed by a subsequent author,³⁸⁹ and the report of several patients with a preceding erythematous or verrucous stage^{390,391} have led several authorities to postulate a link between these two conditions.^{383,390} This seems unlikely in our current state of knowledge. The coexistence of hypomelanosis of Ito and whorled hypermelanosis has been reported.³⁹²

Other features of hypomelanosis of Ito include a female preponderance, a tendency for lesions to become somewhat pigmented in late childhood, a family history in a few cases,³⁹³ and the coexistence in a high percentage of patients of abnormalities of the central nervous system (particularly seizures and mental retardation), eyes, hair, teeth, and musculoskeletal system.^{382,383,394–396} Ileal atresia and leptomenigeal angiomas are other associated abnormalities.^{397,398} Retinoblastoma has been reported in one case.³⁹⁹ Other disease associations include sexual precocity,⁴⁰⁰ choroid plexus papilloma,⁴⁰¹ and multiple nevoid hypertrichosis.⁴⁰² In one patient, a streptococcal exanthem developed in a Blaschko-linear pattern.⁴⁰³

Many different chromosomal abnormalities have been recorded in this condition, leading to a suggestion that this is not a discrete diagnostic condition but is rather a symptom of many different states of mosaicism.^{385,395} The term **pigmentary mosaicism** has been suggested as a better title.⁴⁰⁴ Incontinentia pigmenti type 1, which was subsequently shown to be hypomelanosis of Ito, is associated with an X-autosome translocation involving Xp11. Other chromosomal abnormalities have included trisomy 2 mosaicism⁴⁰⁵ and trisomy mosaicism for chromosomes 7, 12–15, and 18.⁴⁰⁵ Ring chromosome 10, supernumerary X-chromosome ring fragments, and ring chromosome 20 have also been described.^{402,405} It has also been reported in mosaic Turner's syndrome.⁴⁰⁶

Histopathology

The hypopigmented areas show a reduction in melanin pigment in the basal layer, but this is usually not discernible in H&E-stained sections and requires a Masson–Fontana stain for confirmation. Dopa stains show a reduction in staining of melanocytes and sometimes shortening of their dendrites,⁴⁰⁷ and weak tyrosinase immunoreactivity is seen.⁴⁰⁸ A reduction in the number of melanocytes⁴⁰⁹ and vacuolization of basal keratinocytes have been mentioned in some reports but specifically excluded in most.⁴¹⁰

Electron microscopy

Electron microscopy has shown a reduction in melanosomes in melanocytes in the hypopigmented areas and a decrease in the number of melanin granules in keratinocytes.³⁸² Melanosomes appear immature and poorly melanized.⁴⁰⁸ There are isolated reports of aggregation of melanosomes, vacuolization of melanocytes,²⁸⁰ and an increase in the number of Langerhans cells in the epidermis.⁴¹¹

NEVUS DEPIGMENTOSUS

Nevus depigmentosus (achromic nevus) is a rare entity consisting of isolated, circular or rectangular, hypopigmented macules with a predisposition for the trunk and proximal parts of the extremities.^{6,412} In one study, nearly half had only 1 lesion, but one-fifth of patients had more than 10 lesions.⁴¹³ It may also occur along Blaschko's lines or in a systematized pattern, the latter having some clinical resemblance to the pattern seen in hypomelanosis of Ito.^{366,414} In the majority of cases, the lesions are present at birth or appear in early childhood.⁴¹⁵ Lesions remain stable over time.⁴¹³ Melanocytic nevi have developed within nevus depigmentosus lesions in areas exposed to sunlight,⁴¹⁶ and another study reported multiple lentiginous lesions within a zosteriform hypopigmented lesion.⁴¹⁷ Under Wood's lamp, lesions have an off-white accentuation without fluorescence.⁴¹² Diagnostic accuracy can be enhanced using dermoscopy or *in vivo* confocal laser scanning microscopy.^{418–420} Systemic lesions are uncommon,⁴²¹ but an association with unilateral lentiginosis and ILVEN (see p. 786) has been reported.^{422,423} Ipsilateral involvement of the iris has been reported.⁴²⁴ Two sisters who presented with guttate and nummular hypomelanosis in a segmental distribution had numerous melanocytes on biopsy, but the melanocytes had a decreased number of melanosomes.⁴²⁵

One study found a selective defect in eumelanogenesis in nevus depigmentosus, although this remains to be confirmed.⁴²⁶

There are several reports of autologous epidermal grafts being used to treat this condition. They have had mixed success.^{427,428} In another case, misdiagnosed clinically as segmental vitiligo and treated with prolonged intense UVB therapy, lentigines developed in the achromic lesion.⁴²⁹ Suction blister grafting has been performed, with satisfactory results persisting up to 10 years following the grafting procedure.⁴³⁰

Histopathology

The melanin content of lesional skin is decreased compared with that of perilesional normal skin.⁴¹² Melanocytes are said to be normal or slightly reduced in number, although there is reduced dopa activity.^{6,415} In one study, melanocyte counts were significantly reduced with MART-1 and GP-100 stains for melanocytes.⁴¹³ In a study of 30 cases, the number of melanocytes was decreased, but not as much as in vitiligo.²⁷⁵ Lentiginous lesions developing within nevus depigmentosus have shown increased pigmentation within basilar keratinocytes, in the absence of a melanocytic nevus and without an increase in melanocyte numbers.⁴¹⁷

Electron microscopy³⁶⁶

Melanosomes are normal in size, but there may be abnormal aggregation of them within melanocytes.⁴²⁶ One study showed a reduction of melanosomes in melanocytes.⁴¹⁵ Degradation of melanosomes within autophagosomes of melanocytes has been noted. Melanosomes are decreased in number in keratinocytes, suggesting impaired transfer.⁴²¹

PITYRIASIS ALBA

Pityriasis alba consists of variably hypopigmented, slightly scaly patches, varying from 0.5 to 6 cm in diameter with a predilection for

the face, neck, and shoulders of dark-skinned atopic individuals.^{431–433} It is more common in males than females, and most patients are between 6 and 16 years of age.⁴³⁴ The etiology is unknown, although it has been regarded as postinflammatory hypopigmentation following eczema.⁴³¹ It has been reported in patients with atopic eczema.⁴³⁵ The role of organisms is controversial; none has been confirmed as a causal factor.⁴³⁴

A supposed variant with extensive nonscaling macules involving the lower part of the trunk has been reported, but there is no real evidence that this is the same process.^{432,433}

Pityriasis alba is a frequent reason for medical consultation because of its chronic course, tendency to relapse, and esthetic impact.⁴³⁶ Topical corticosteroids are often used in the treatment of this condition even though no formal study has assessed their efficacy.⁴³⁶ However, long-term use of topical corticosteroids is not desirable, particularly on the face. Tacrolimus ointment (0.5%) has been reported to produce satisfactory results.⁴³⁶ Note that tacrolimus is not approved in some countries for pediatric use. Good results have been obtained with use of the 308-nm xenon chloride excimer laser.⁴³⁷ Calcitriol and tacrolimus produced similar degrees of repigmentation in cases of endemic pityriasis alba from Mexico.⁴³⁸

Another suggested clinical variant is pigmented pityriasis alba, in which a central zone of bluish hyperpigmentation develops in a scaly, hypopigmented patch.⁴³⁹ A dermatophyte was present in 65% of these cases.⁴³⁹

Histopathology

There are no detailed studies of the usual facial type of pityriasis alba. In a personally studied case, there was mild hyperkeratosis, focal parakeratosis, and focal mild spongiosis with prominent exocytosis of lymphocytes.⁴⁴⁰ There was also a mild superficial perivascular inflammatory cell infiltrate in the dermis. Melanin pigmentation of the basal layer was markedly reduced, but there was no melanin incontinence.⁴⁴⁰ Melanocytes were normal in number. This conforms with one other reported case⁴⁴¹ and is in agreement with the experience of the editor (JWP) (Fig. 10.8). A reduced number of melanocytes with smaller melanosomes is another suggested finding.⁴³⁹ Melanocytes were normal in number in a study of 56 cases.⁴⁴²

Figure 10.8 Pityriasis alba. There is only a slight degree of spongiosis. A mild perivascular lymphocytic infiltrate is present in the papillary dermis. There is reduced melanin pigmentation of the basal layer, but numbers of melanocytes are normal. (H&E)

A study of the 'extensive' variant showed reduced basal pigmentation, a decreased number of functional melanocytes on the dopa preparation, and a reduction in the number and size of melanosomes.⁴³²

A study of 39 Mexican patients showed follicular spongiosis and keratotic follicular plugging as a prominent feature – a change usually associated with the follicular papules of atopic dermatitis (see p. 110).⁴⁴³ There was irregular melanization of the basal layer.⁴⁴³

POSTINFLAMMATORY LEUKODERMA

Hypopigmented areas may develop during the course of a number of inflammatory diseases of the skin, usually during the resolving phases.⁶ Examples include the various eczematous dermatitides, psoriasis, discoid lupus erythematosus, pityriasis rosea, variants of parapsoriasis, lichen sclerosus et atrophicus, syphilis, and the viral exanthems.⁶ Uncommonly, hypopigmentation may follow lichen planus and other lichenoid eruptions. It may occur in the vicinity of the injection site, following the injection of corticosteroids;⁴⁴⁴ it may follow the application of imiquimod cream.⁴⁴⁵ Extensive hypopigmentation followed the commencement of antiretroviral treatment in an HIV-seropositive African woman.⁴⁴⁶ Hypomelanotic lesions may occur at an early stage, albeit uncommonly, in some of the following diseases: alopecia mucinosa, sarcoidosis, mycosis fungoides, pityriasis lichenoides chronica, pityriasis versicolor (tinea versicolor), onchocerciasis, yaws, and leprosy.⁶

The mechanism of the hypopigmentation in many of these conditions is thought to be a block in the transfer of melanosomes from melanocytes to keratinocytes; this has been demonstrated in a case of hypopigmented sarcoidosis.^{447,448} In the lichenoid dermatoses, damage to melanocytes may also contribute. In pityriasis versicolor, melanosomes are poorly melanized; impaired transfer is also present.

Various mechanisms have been proposed for the hypopigmentation of lesions in indeterminate and tuberculoid leprosy (see p. 660).

Histopathology

There is a reduction in melanin pigment in the basal layer, although not a complete absence. Melanocytes are usually normal in number. Pigment-containing melanophages are sometimes present in the upper dermis, particularly in black patients. Residual features of the preceding or concurrent inflammatory dermatosis may also be present.

Hyperkeratosis was present in the lesions of a patient with confetti-like leukoderma that followed psoralen photochemotherapy;⁴⁴⁹ the hyperkeratosis has not been present in other cases.^{450–452}

NEVUS ANEMICUS

Nevus anemicus is an uncommon congenital disorder in which there is usually a solitary asymptomatic patch that is paler than the surrounding normal skin.⁴⁵³ Its margin is irregular, and there may be islands of sparing within the lesion.⁴⁵⁴ The pale area averages 5–10 cm in diameter. There is a female predominance.⁴⁵⁵ There is a predilection for the upper trunk, although involvement of the face, neck, and extremities occurs.^{455,456} A variant with multiple lesions on the arms has been reported.⁴⁵⁷ Nevus anemicus sometimes occurs in association with neurofibromatosis,⁴⁵⁸ phakomatosis pigmentovascularis, or port wine stains.⁴⁵⁹ Onset in one patient was at age 21 years, suggesting the likelihood of an acquired variant of nevus anemicus.⁴⁵⁵ A case of facial nevus anemicus has been associated with melanosis bulbi on the same side – an example of didymosis (nevic lesions occurring together but differing from one another and from the normal background tissue).⁴⁶⁰ A variant of nevus anemicus appears to have arisen at the site of prior removal of an epidermal cyst.⁴⁶¹ **Bier's spots** have a similar appearance, but they are permanent, often associated with venous stasis.

They probably result from anatomical or functional damage to small blood vessels.^{462,463}

Nevus anemicus is regarded as a pharmacological nevus in which the pallor is attributable to increased sensitivity of the blood vessels in the area to catecholamines.⁴⁶⁴ It has been found that the vessels do not respond normally to proinflammatory cytokines, at least at the level of E-selectin expression.⁴⁶⁵ **Nevus oligemicus** is a related entity in which there is livid erythema rather than pallor.^{466,467} It is believed to result from vasoconstriction of the deep vascular plexus, with vasodilatation of superficial dermal vessels, related to abnormal responses of adrenergic receptors.⁴⁶⁸

Histopathology

No abnormalities have been shown by light or electron microscopy in nevus anemicus. Nevus oligemicus biopsies show dilated vessels in the superficial dermis, occasionally associated with a few perivascular lymphocytes.^{468–470}

DISORDERS CHARACTERIZED BY HYPERPIGMENTATION

The disorders characterized by hyperpigmentation constitute a heterogeneous group of diseases comprising a bewildering number of rare conditions. Japanese people are predisposed to many of the entities discussed here. Several factors are taken into consideration in the clinical categorization of these various disorders, including the distribution, arrangement, and morphology of individual lesions as well as the presence or absence of hypopigmented areas.^{471,472} Four clinical categories of hyperpigmentation can be recognized:

1. *Diffuse hyperpigmentation*: generalized hyperpigmentary disorders (scleroderma, Addison's disease, myxedema, Graves' disease, malnutrition including pellagra, chronic liver disease including hemochromatosis and Wilson's disease, porphyria, folate and vitamin B₁₂ deficiency, heavy metal toxicity, and the ingestion of certain drugs and chemicals), universal acquired melanosis, the generalized melanosis that may develop in malignant melanoma, and in some cases of pheochromocytoma.⁴⁷³
2. *Localized (patchy) hyperpigmentation*: ephelis (freckle), café-au-lait spots, macules of Albright's syndrome, macules of Peutz–Jeghers syndrome, macules of Laugier–Hunziker syndrome, Becker's nevus, acromelanosis, melasma, fixed drug eruption, frictional melanosis, notalgia paresthetica, familial progressive hyperpigmentation and idiopathic eruptive macular pigmentation; the boys who presented with pigmented hypertrichotic lesions on the upper inner thighs with variable involvement of the genitalia, trunk, and limbs, associated with insulin-dependent diabetes, are difficult to classify.⁴⁷⁴
3. *Punctate, reticulate hyperpigmentation (including whorls and streaks)*: Dowling–Degos disease, Kitamura's disease, Naegeli–Franceschetti–Jadassohn syndrome, dermatopathia pigmentosa reticularis, macular amyloidosis, 'ripple neck' in atopic dermatitis, hereditary diffuse hyperpigmentation, incontinentia pigmenti, prurigo pigmentosa, confluent and reticulated papillomatosis, patterned hypermelanosis, and chimerism; generalized mottled pigmentation with acral blistering can also be grouped here.⁴⁷⁵
4. *Dyschromatosis (hyperpigmentation and hypopigmentation)*: dyskeratosis congenita, dyschromatosis symmetrica hereditaria (Dohi), dyschromatosis universalis hereditaria, familial gigantic melanocytosis, heterochromia extremitarum,⁴⁷² Fanconi anemia,⁴⁷⁶ and hereditary congenital hypopigmented and hyperpigmented macules.⁴⁷⁷

Theoretically, the hyperpigmentation observed in these various conditions could result from increased basal pigmentation and/or melanin incontinence. Alterations in the epidermal configuration can also produce apparent pigmentation of the skin.

Although there is some variability in the histopathological features reported in some of the disorders of hyperpigmentation, the following subclassification provides a useful approach to a biopsy from such a disease:

- *Disorders with basal hyperpigmentation (mild melanin incontinence is sometimes present also):* generalized hyperpigmentary disorders, universal acquired melanosis, acromelanosis (increased melanocytes were noted in one report), familial progressive hyperpigmentation, idiopathic eruptive macular pigmentation, dyschromatosis symmetrica hereditaria, dyschromatosis universalis, patterned hypermelanosis, chimerism, melasma, acquired brachial dyschromatosis, ephelis (freckle), café-au-lait spots, macules of Albright's syndrome, Laugier–Hunziker syndrome, Bannayan–Riley–Ruvalcaba syndrome, and Peutz–Jeghers syndrome, and Becker's nevus (melanosis)
- *Disorders with epidermal changes:* Dowling–Degos disease (the epidermal changes resemble those of solar lentigo), Kitamura's disease (the epidermal changes resembling Dowling–Degos disease but with intervening epidermal atrophy also), and confluent and reticulated papillomatosis of Gougerot–Carteaud (the epidermal changes are those of papillomatosis)
- *Disorders with striking melanin incontinence:* postinflammatory melanosis, prurigo pigmentosa, generalized melanosis in malignant melanoma, dermatopathia pigmentosa reticularis, Naegeli–Franceschetti–Jadassohn syndrome, incontinentia pigmenti, and late fixed drug eruptions
- *Disorders with melanin incontinence and epidermal atrophy or 'dyskeratotic' cells:* dyskeratosis congenita, frictional melanosis, notalgia paresthetica, 'ripple neck' in atopic dermatitis, active fixed drug eruptions, and active prurigo pigmentosa.

Fixed drug eruptions and dyskeratosis congenita are discussed with the lichenoid reaction pattern on pages 53 and 77, respectively. Confluent and reticulated papillomatosis is considered on page 589.

GENERALIZED HYPERPIGMENTARY DISORDERS

As mentioned previously, generalized cutaneous hyperpigmentation can be seen in a number of metabolic, endocrine,⁴⁷⁸ hepatic, and nutritional disorders, as well as following the application of topical calcipotriene (calcipotriol)⁴⁷⁹ and the intake of certain drugs⁴⁸⁰ and heavy metals.⁴⁸¹ Hyperpigmentation may follow sympathectomy.⁴⁸² It may also occur in the POEMS (Crow–Fukase) syndrome⁴⁸³ (see p. 1085).

Histopathology

Biopsies of the pigmented skin are not often taken from individuals with these conditions. There is an increase in melanin in the lower layers of the epidermis and sometimes a small amount of pigment in the dermis. Of interest is the finding of large nuclei in the keratinocytes of the pigmented skin in some megaloblastic anemias.^{484,485}

Hemosiderin pigment was present around dermal capillaries and sweat glands in two cases of hyperpigmentation associated with hyperthyroidism.⁴⁸⁶

UNIVERSAL ACQUIRED MELANOSIS

Universal acquired melanosis is an extremely rare condition, also known as the 'carbon baby' syndrome. It is characterized by progres-

sive pigmentation of the skin during childhood, resembling that seen in black races.⁴⁸⁷

Histopathology

In one reported case, there was hyperpigmentation of the epidermis and an increase in type III and IV (negroid pattern) melanosomes in melanocytes.⁴⁸⁷ The same basilar hypermelanosis has been repeatedly described,⁴⁸⁸ sometimes associated with hyperkeratosis⁴⁸⁹ or blunting of the rete ridges.⁴⁹⁰

ACROMELANOSIS

Acromelanosis refers to the presence of pigmented patches and macules on the dorsal surface of the phalanges, usually in dark-skinned individuals.^{471,472} Several clinical variants have been recognized on the basis of the distribution of the pigment and the progression of the disorder.^{472,491} Hyperpigmentation of the distal phalanges of both hands and feet is usually a prominent feature of dark-skinned newborns, as is hyperpigmentation of the external genitalia and areola.⁴⁹² Periungual hyperpigmentation has also been reported in a small number of fair-skinned newborns.⁴⁹² It fades with time.

Histopathology

Basal hyperpigmentation is the usual finding, although an increase in basal melanocytes with associated acanthosis has also been reported.⁴⁹¹

FAMILIAL PROGRESSIVE HYPERPIGMENTATION

Patches of hyperpigmentation are present at birth in this rare genodermatosis.⁴⁹³ They increase in size and number with age. Pigmentation of the palate, tongue, and gingiva has also been reported.⁴⁹⁴ Eventually, a large percentage of the skin and mucous membranes becomes hyperpigmented.⁴⁹³ Familial progressive hyperpigmentation has been associated with mutations activating the KIT receptor ligand.⁴⁹⁵

Histopathology⁴⁹³

The most striking change is an increase in melanin pigment within the epidermis, especially in the basal layer. There is some concentration at the tips of the rete ridges. The case of Zhang and Zhu also showed slight hyperkeratosis, vasodilatation, a mild perivascular lymphohistiocytic infiltrate, and pigmentary incontinence.⁴⁹⁶

IDIOPATHIC ERUPTIVE MACULAR PIGMENTATION

Idiopathic eruptive macular pigmentation is an exceedingly rare condition characterized by asymptomatic, pigmented macules involving the neck, trunk, and proximal extremities.^{497,498} Fewer than 30 cases have been reported.⁴⁹⁹ This idiopathic disorder involves children and adolescents; one case was associated with pregnancy and Hashimoto thyroiditis.⁴⁹⁹ The lesions usually appear abruptly. Spontaneous resolution can be expected within several months to a few years,^{497,500} although a case lasting 21 years, with several episodes of spontaneous resolution followed by recurrences, has been reported.⁵⁰¹

Histopathology

There is increased pigmentation of the basal layer, pigmentary incontinence with many melanophages in the upper dermis, and a sparse perivascular lymphohistiocytic infiltrate.⁵⁰² The changes are similar to those seen in erythema dyschromicum perstans, to which this disorder has been likened,⁵⁰² others disagree.⁴⁹⁸ A variant has been described that also features papillomatosis.^{503,504}

Differential diagnosis

The variant of idiopathic eruptive macular pigmentation with papillomatosis bears a close microscopic resemblance to acanthosis nigricans and confluent and reticulated papillomatosis. In contrast to the latter disorder, idiopathic eruptive macular pigmentation occurs in a slightly younger age group, develops abruptly, does not become confluent, and tends not to be pruritic.⁵⁰⁴

DYSCHROMATOSIS SYMMETRICA HEREDITARIA

Dyschromatosis symmetrica hereditaria (OMIM 127400), also known as reticulate acropigmentation of Dohi,⁵⁰⁵ consists of freckle-like lesions on the dorsum of the hands and feet with scattered depigmented macules in between.^{471,472,506–508} Complications include neurologic abnormalities (dystonia, mental deterioration, and brain calcification),⁵⁰⁹ apparent acral hypertrophy due to interstitial dermal mucin deposition,⁵¹⁰ and a combination of long forearm hair, hypopigmented and hyperpigmented hairs, and dental anomalies.⁵¹¹ The age of onset is approximately 6 years. Cases from Japan, China, and Korea generally have an autosomal dominant pattern of inheritance. This form of the disease results from mutations in the double-stranded RNA-specific adenosine deaminase (*ADAR/DSRAD*) gene located at 1q11–q21.^{512–516} Another study mapped this gene to 1q21–q22,⁵¹⁷ whereas the OMIM gene map lists it at 1q21.3. Another study lists the gene location as 1q11–q12.⁵¹⁸ The gene encodes the enzyme responsible for the deamination of adenosine to inosine,⁵¹³ as such, it is an RNA editing enzyme.⁵¹⁹ A number of novel mutations of the *ADAR1* gene have been reported.^{520–522} Several cases reported from the Middle East had autosomal recessive inheritance.⁵²³ Nothing is known about the genetic abnormality in these cases.

Both dyschromatosis symmetrica hereditaria and dyschromatosis universalis hereditaria (see later) are inherited pigmentary skin disorders. In the latter condition, skin lesions occur earlier (first month of life) and truncal involvement is usually present, whereas the lesions in dyschromatosis symmetrica hereditaria are predominantly acral in location.⁵¹³

Histopathology

The epidermis shows increased pigmentation, mainly basal, in the hyperpigmented areas and reduced pigmentation, sometimes accompanied by a reduction in the number of melanocytes, in hypopigmented areas.⁴⁷² Ultrastructurally, melanocytes in hypopigmented areas show mitochondrial degeneration and cytoplasmic vacuolization, whereas those in hyperpigmented areas show scattered small or immature melanosomes in melanocytes and dispersed or aggregated melanosomes in adjacent keratinocytes, indicating active melanosome transfer.⁵⁰⁹

DYSCHROMATOSIS UNIVERSALIS HEREDITARIA

Dyschromatosis universalis hereditaria (OMIM 127500) is the prototype condition for a group of dyschromatoses characterized by areas of hypopigmentation and hyperpigmentation.^{471,524–526} The absence of atrophy and telangiectasia distinguishes this group from the poikilodermas.⁴⁷¹ Onset is in early childhood, usually the first few months of life, with involvement being most prominent on the trunk and extremities.⁵¹³ This contrasts with dyschromatosis symmetrica hereditaria (discussed previously) in which lesions are almost always acral in location. Clinical variants have been described,^{527–531} and one case has been associated with thrombocytopenia, hypochromic microcytic anemia, and unilateral conduction deafness.⁵³²

The gene responsible maps to chromosome 6q24.2–q25.2.⁵¹³ Although most cases have had an autosomal dominant inheritance, an

autosomal recessive inheritance seems likely in some cases.⁵³³ In the autosomal recessive variant, a new locus on 12q21–q23 appears to be involved.⁵³⁴ A study of a Chinese family identified ABCB6 as a pathogenic gene associated with dyschromatosis universalis hereditaria.⁵³⁵

Histopathology

There is variable epidermal pigmentation that may be accompanied by some pigment incontinence. The number of melanocytes is sometimes reduced in the hypopigmented areas.⁵²⁷ Other descriptions have included mild hyperkeratosis, pigmentation – including coarse melanin granules – in lower layers of the epidermis, pigment incontinence with dermal melanophages, and sparse perivascular lymphohistiocytic infiltrates.⁵³⁶

PATTERNED HYPERMELANOSIS

The term ‘patterned hypermelanosis’ is proposed for several rare dermatoses with overlapping features that have been reported in the past by different names. They are characterized by linear, whorled, or reticulate areas of hyperpigmentation.⁴⁷² Although the term ‘zosteriform’ has been used to describe the pattern of the pigmentation in some of these cases, it has been pointed out that this term has not always been used correctly; the hyperpigmentation usually follows Blaschko’s lines (the boundary lines separating areas of the skin subserved by different peripheral nerves) and not the courses of the nerves themselves as in a zosteriform pattern.^{537–540} A review of 54 children with segmental, linear, or swirled hyper- and/or hypopigmentation along the lines of Blaschko revealed that 16 had extracutaneous manifestations.⁵¹⁸ Another study in which pigmentary anomalies along the lines of Blaschko were associated with abnormalities of the central nervous system included a few patients with incontinentia pigmenti and hypomelanosis of Ito; most cases could not be categorized further.⁵⁴¹ In another report, hyperpigmentation along the lines of Blaschko was associated with chromosome 14 mosaicism.⁵⁴² Dyspigmentation has also been associated with mosaic chromosome 5p tetrasomy⁵⁴³ and with trisomy 20 mosaicism.⁵⁴⁴

Included in the patterned hypermelanoses are cases reported as ‘linear and whorled nevoid hypermelanosis’,^{537,539,545–553} ‘reticulate hyperpigmentation distributed in a zosteriform fashion’,⁵⁵⁴ ‘progressive cribriform and zosteriform hyperpigmentation’,^{555,556} ‘congenital curvilinear palpable hyperpigmentation’,⁵⁵⁷ ‘zebra-like hyperpigmentation’,⁵⁵⁸ ‘progressive zosteriform macular pigmented lesions’,⁵⁵⁹ ‘dyschromia in confetti’ (following topical immunotherapy with diphenylcyclopropenone),⁵⁶⁰ and ‘infant with abnormal pigmentation’.⁵⁶¹ A mottled pigmentation is seen in mosaic subclinical melanoderma, a condition observed when photo-exposed skin of adults is examined by ultraviolet light.⁵⁶² The term ‘patterned hypermelanosis’ is not applicable to well-defined entities such as incontinentia pigmenti and the reticulate acral pigmentations of Kitamura and of Dowling and Degos (see p. 337). Streaks of hyper- and hypopigmentation can be seen in the Pallister–Killian (Killian–Teschler–Nicola) syndrome (OMIM 601803) associated with tetrasomy of chromosome 12p.^{563–565}

Histopathology

In all cases, there has been an increase in melanin pigment in the basal layer. Pigment incontinence has been present in several cases.⁵⁵⁹ A mild increase in the number of melanocytes, usually demonstrable only when quantitative studies are made, has been reported in a few cases.^{537,558,561}

FAMILIAL GIGANTIC MELANOCYTOSIS

This exceedingly rare condition, which may have autosomal dominant inheritance, was originally described as ‘familial melanopathy with

gigantic melanocytes'.⁵⁶⁶ It is characterized by a diffuse brown hyperpigmentation, admixed with raindrop hypopigmentation, which affects mainly exposed areas but also to a lesser extent unexposed areas.^{566,567} The pigmentary changes are accompanied by sparse axillary and pubic hair and light-colored scalp and body hair.

The cause of the disorder is unknown, but melanocytes in both hyper- and hypopigmented skin seem to be unable to deliver melanin to the surrounding keratinocytes.⁵⁶⁶

Histopathology⁵⁶⁶

The key histological feature is the presence of abnormally large melanocytes, at least three times the size of normal melanocytes. They are present in both hyper- and hypopigmented zones, but there are fewer melanocytes in the hypopigmented areas. There are areas with hyperpigmented basal cells alternating with poorly pigmented skin.

Electron microscopy

There are abundant stage IV melanosomes in melanocytes.⁵⁶⁷

CHIMERISM

Chimerism results from double fertilization of an ovum, producing an individual (a chimera) with differing sets of chromosomes.⁵⁶⁸

Abnormalities of skin pigmentation, usually in the form of irregular areas of hyperpigmentation, are a rare manifestation of the chimeric state.^{568,569}

Histopathology

Melanin is increased in the basal layers of the epidermis in the hyperpigmented lesions.⁵⁶⁸

MELASMA

Melasma (chloasma) is an acquired, chronic, recurrent symmetrical hyperpigmentation of the forehead and cheeks that develops in some women, especially those living in areas of intense UV radiation, who are pregnant or taking oral contraceptives.⁵⁷⁰⁻⁵⁷³ Its incidence in pregnancy varies from 15 to 50% or more;⁵⁷⁴ this figure varies with ethnicity. It has also been reported in women taking isotretinoin⁵⁷⁵ or hormone replacement therapy;⁵⁷⁶ the forearms are sometimes involved in this latter group.^{577,578} Coexistence of melasma and vitiligo has been reported.⁵⁷⁹ The hormonal basis for melasma is poorly understood. There is increased expression of α -melanocyte-stimulating hormone in lesional skin⁵⁸⁰ and increased expression of stem cell factor in the dermis and of its receptor c-kit in the epidermis.⁵⁸¹

There have been very few well-conducted trials on the treatment of melasma, which makes the comparison of outcomes difficult.⁵⁷³ A review of various clinical trials was published in 2006.⁵⁸² Therapies include use of broad-spectrum sunscreens, topical hydroquinone, retinoic acid (tretinoin), and azelaic acid;⁵⁸² the triple combination of fluocinolone acetonide, hydroquinone, and tretinoin;⁵⁸³ chemical peels;⁵⁸⁴ laser treatment; and intense pulsed light therapy.⁵⁸² A trial of topical rucinol serum produced skin lightening after 3 months of use;⁵⁸⁵ rucinol inhibits the activity of both tyrosinase and TRP-1.⁵⁸⁵ Interestingly, in a study of vitiligo treatment with narrowband UVB, patients with both vitiligo and melasma had a better prognosis for repigmentation of the face and extremities than those with vitiligo alone, whereas the reverse was the case for truncal lesions.⁵⁷⁹

Histopathology

There is increased melanin in the epidermis, particularly in the basal layers. Melanin pigment is located in a 'cap' overlying the keratinocyte

Figure 10.9 Melasma. There is increased melanin in the epidermis. Melanin can be seen to form a 'cap' over several keratinocyte nuclei (arrowheads), although it is also located elsewhere within these cells. Pigment is also deposited in the dermis, with some of it residing within melanophages. (H&E)

nuclei.⁵⁸⁶ One study showed that melanocytes were increased in most cases but that some cases showed a normal or even a decreased number.⁵⁸⁶ Another study found normal melanocyte numbers in all cases.⁵⁸⁷ Melanosomes are increased in basal and suprabasal keratinocytes.⁵⁸⁶ Melanocytes have increased numbers of dendrites.⁵⁸⁷ Mild pigment incontinence is sometimes present (Fig. 10.9). Solar elastosis is more prominent than in normal skin.⁵⁸⁸ Mast cells are also increased in number.⁵⁸⁸

ACQUIRED BRACHIAL DYSCHROMATOSIS

Acquired brachial (cutaneous) dyschromatosis was applied to the asymptomatic, gray-brown patches of pigmentation, occasionally interspersed with hypopigmented macules, found predominantly on the dorsum of the forearms, mostly bilateral, of middle-aged patients.⁵⁸⁹ There was a predilection for women, many of whom had been taking antihypertensive drugs, especially angiotensin-converting enzyme (ACE) inhibitors.⁵⁸⁹ Many patients also had Civatte's poikiloderma of the neck.

Histopathology⁵⁸⁹

The pigmented lesions showed epidermal atrophy, increased basal layer pigmentation, superficial telangiectases, and actinic elastosis. There was no pigmentary incontinence or amyloid.

The hypopigmented macules showed a decrease in pigmentation of the basal layer. On ultrastructural examination, the pigmented macules have shown increased numbers of melanosome complexes within basilar keratinocytes.⁵⁹⁰

EPHELIS (FRECKLE)

Ephelides (freckles) are small, well-defined, pigmented macules 1–2 mm in diameter with a predilection for the face, arms, and shoulder regions of fair-skinned individuals. They appear at an early age and may follow an episode of severe sunburn.

Figure 10.10 Freckle (ephelis). Melanin is increased in the basal layers of the epidermis, but melanocytes are normal in number and morphology. (H&E)

Histopathology

The epidermis appears normal in structure. The basal cells in the affected areas are more heavily pigmented with melanin than those in the surrounding skin, and there is usually sharp delimitation of the abnormal areas from the normal (Fig. 10.10). There are normal numbers of melanocytes.⁵⁹¹

CAFÉ-AU-LAIT SPOTS

Café-au-lait spots are uniformly pigmented, tan to dark brown macules that vary in size from small, freckle-like lesions to large patches 20 cm or more in diameter.⁵⁹² They may be present at birth or develop within the first few years of life.⁵⁹³ Some cases appear to develop early in embryogenesis, possibly as early as 3 or 4 weeks of gestation.⁵⁹⁴ They are found in approximately 15% of individuals.^{595–597} They are not increased in patients with tuberous sclerosis, contrary to common belief.⁵⁹⁸ Multiple café-au-lait spots are a feature of neurofibromatosis;^{593,597,599} axillary freckling is often also present in these cases (see p. 1050). Café-au-lait spots have also been reported in Bloom's syndrome, Cowden's disease, Fanconi's anemia, ring chromosome syndromes, ataxia-telangiectasia,^{597,600} nevoid basal cell carcinoma syndrome,^{601,602} Legius syndrome, and Noonan's syndrome.⁶⁰³ Patients with Fanconi's anemia (OMIM 227650), an autosomal recessive disorder due to a mutation in the *FANCC* gene, may also have macules of 'guttate' hypopigmentation.⁴⁷⁶ A large achromic patch has also been reported in the Silver-Russell syndrome (OMIM 180860), in which cutaneous dyschromia, usually in the form of café-au-lait macules, is combined with musculoskeletal abnormalities, genitourinary malformations, and craniofacial dysmorphism.⁶⁰⁴ Familial, multiple café-au-lait spots have also been reported without any evidence of coexisting disease.⁶⁰⁵ They have been reported on the upper and lower eyelids in one patient in a pattern analogous to the 'kissing' nevus.⁶⁰⁶ Multiple cellular neurothekeomas have developed in a café-au-lait macule in a child.⁶⁰⁷

Histopathology

In H&E preparations, the lesions resemble freckles, with basal hyperpigmentation but no apparent increase in the number of melanocytes. However, quantitative studies have shown a slight increase in melanocytes, which are accommodated in focally elongated rete ridges.^{608,609}

Figure 10.11 Giant melanosomes. A cluster of macromelanosomes can be identified within the basal layer (arrow). However, this particular lesion is a lentigo, not a café-au-lait macule. (H&E)

This was confirmed in one ultrastructural study.⁶¹⁰ Giant melanin granules (macromelanosomes), measuring up to 6 μm in diameter and recognizable on light microscopy, can be seen in café-au-lait spots in many patients with neurofibromatosis.⁶¹¹ The diagnostic significance of macromelanosomes is diminished by their absence in some children with neurofibromatosis and their presence in normal skin and other pigmented macular lesions (Fig. 10.11).^{612–615}

Electron microscopy

Many subepidermal and intraepidermal nerves are present in lesional skin.⁶⁰⁹ Macromelanosomes are present in some melanocytes.⁶¹⁰

MACULES OF ALBRIGHT'S SYNDROME

Albright's syndrome (McCune–Albright syndrome; OMIM 174800) is characterized by the triad of polyostotic fibrous dysplasia, sexual precocity – especially in the female, and pigmented macules.⁶¹⁶ These macules are large, often unilateral, and related to the side of the bone lesions. The outline of the macules is very irregular, in contrast to that of café-au-lait spots. The macules may follow Blaschko's lines.⁶¹⁷

The syndrome is associated with a postzygotic somatic mutation of the *GNAS1* gene that encodes the α subunit of the G_s protein. The gene map locus is 20q13.2.⁶¹⁸ This condition shows genomic imprinting, a process whereby genetic alleles responsible for a phenotype are derived from one parent only.⁶¹⁹

Histopathology

The lesions resemble freckles, showing hyperpigmentation of the basal layer. Rarely, macromelanosomes can be identified.⁶¹³

LAUGIER–HUNZIKER SYNDROME

The Laugier–Hunziker syndrome is characterized by melanotic pigmentation of the mouth and lips that is frequently accompanied by longitudinal melanonychia.^{5,620–623} In a small number of cases, there are dark palmoplantar and interdigital lesions. Pigmented macules may also develop about the nails. Conjunctival, vulval, and penile pigmentation occur rarely.^{624,625} Pigmented fungiform papillae have also been found in this disorder, but it is not unique to Laugier–Hunziker

syndrome because it also occurs as a normal variant in dark-skinned individuals.^{626,627} There are usually no associated internal disorders. The occurrence of a hypocellular marrow in one patient may have been a fortuitous association.⁶²⁸ Addison's disease developed in another patient with features suggestive of Laugier–Hunziker syndrome.⁶²⁹ Actinic lichen planus is another association, possibly fortuitous.⁶³⁰ Onset occurs between 20 and 50 years of age.⁶²² Familial occurrence involving three members of the same family has been reported.⁶³¹ Dermoscopy of the pigmented macules on the palms and soles shows a parallel furrow pattern.⁶³² Studies have also shown longitudinal brown-gray lines and bands in the nails and a brownish, reticulated pattern with linear or curvilinear vessels in the buccal mucosa.⁶³³

Histopathology

The changes are similar in all lesions with acanthosis, basal hypermelanosis, and some melanin incontinence with scattered melanophages in the upper dermis.⁶²² Increased numbers of mildly atypical melanocytes were present in the epidermis and mucosa of one patient,⁶³⁴ whereas other patients have had normal numbers of morphologically normal melanocytes.⁶³⁵ Some large melanosomes have been noted on electron microscopy.⁶²¹

PEUTZ–JEGHERS SYNDROME

The autosomal dominant Peutz–Jeghers syndrome (OMIM 175200) is characterized by the association of gastrointestinal polyposis with the presence of pigmented macules on the buccal mucosa, lips, perioral skin, and sometimes the digits.^{5,636,637} Patients with this syndrome have an increased risk of developing cancer at a relatively young age. The most common malignancies, in order of frequency, are colorectal, breast, small bowel, gastric, and pancreatic.⁶³⁸ There appears to be genetic heterogeneity, although most cases involve the serine/threonine kinase (*STK11/LKB1*) gene on chromosome 19p13.3.⁶³⁹ It encodes the protein LKB1, which regulates p53-mediated apoptotic pathways.⁶⁴⁰ Mutations in the part of the gene involved in substrate recognition are more frequently associated with malignancies than mutations in the part of the gene involved in ATP binding and catalysis.⁶⁴¹ A case associated with primary melanoma of the rectum has been reported.⁶⁴² The **Cronkhite–Canada syndrome** (OMIM 175500) is also characterized by intestinal polyposis and lentigo-like macules, commonly on the face, extremities, and the palms.⁶⁴³ The pigmentation tends to be diffuse rather than spotted as in the Peutz–Jeghers syndrome. The etiology is unknown.

Histopathology

There is basal hyperpigmentation in the pigmented macules. There are conflicting views regarding whether the melanocytes are quantitatively increased.^{644,645} Basal hyperpigmentation, without an increase in melanocytes, is seen in the Cronkhite–Canada syndrome.⁶⁴³

BANNAYAN–RILEY–RUVALCABA SYNDROME

Bannayan–Riley–Ruvalcaba (Ruvalcaba–Myhre–Smith) syndrome (OMIM 153480) combines juvenile polyposis coli, macrocephaly, and pigmented macules limited to the shaft and glans of the penis.⁶⁴⁶ It results from mutations in the *PTEN* gene on chromosome 10q23.31.⁶⁴⁶ It is allelic with Cowden's syndrome (see p. 909).⁶⁴⁷

BECKER'S NEVUS

Becker's nevus (melanosis) is usually found in the region of the shoulder girdle of young men as unilateral, hyperpigmented areas of

somewhat thickened skin.^{614,648} The front of the chest is another common site, but lesions may occur on any area of the body,⁶⁴⁹ including the face.⁶⁵⁰ Multiple lesions are rare.⁶⁵¹ Giant bilateral Becker's nevus is extremely rare.⁶⁵² The male-to-female ratio ranges from 4:1 to 6:1.⁶⁵³ Hypertrichosis may develop after the pigmentation, but is not invariable.⁶⁵⁴ A Becker's nevus is usually acquired in adolescence, but a congenital onset has been recorded,^{655,656} as have familial cases.^{657,658} Its prevalence in a large series of French military recruits was 0.52%.⁶⁵⁹ It is more common in young people with fair skin.⁶⁶⁰ Occasionally, lesions have been said to follow severe sunburn. Lesional tissue has been found to have an increased level of androgen receptors, suggesting that heightened local androgen sensitivity may result in the hypertrichosis.⁶⁶¹ Various skeletal malformations have been reported in individuals with a Becker's nevus.^{662–664} Other associations have included neurofibromatosis,⁶⁶⁵ segmental nevus depigmentosus (a possible example of twin spotting),⁶⁶⁶ a connective tissue nevus,^{667,668} acquired superficial angiomas,⁶⁶⁹ an accessory scrotum,⁶⁷⁰ limb deformities, and areolar hypoplasia.^{671,672} Diseases reported to have developed in a Becker's nevus include eczematous dermatitis and prurigo nodularis,⁶⁷³ hypohidrosis,⁶⁷⁴ acneiform lesions,^{654,675,676} lichen planus,⁶⁵⁶ localized scleroderma,⁶⁴⁹ and a basal cell carcinoma combined with a melanocytic nevus and a smooth muscle hamartoma.⁶⁷⁷ An eczematous dermatitis confined to a Becker's nevus lesion has been reported; due to the absence of a hypopigmented halo, it was considered an example of an isotopic response rather than Meyerson's phenomenon.⁶⁷⁸

Treatment is usually with laser therapy. Ablative lasers usually leave scarring. Q-switched lasers are used in pigmented variants, but several treatments are necessary. The best results (in pigmented lesions) have been obtained with erbium:YAG lasers.^{659,679}

Histopathology

The epidermal changes are variable, but usually there is acanthosis and sometimes mild papillomatous hyperplasia (Fig. 10.12). The changes may resemble those seen in an epidermal nevus (see p. 784). In Becker's nevus, the elongated rete ridges sometimes have flat rather than pointed tips, although in the editor's experience they are more often pointed – certainly to a greater degree than normally encountered in dermatofibroma (Fig. 10.13). There is variable hyperpigmentation of the basal layer with some melanophages in the dermis. Melanocyte proliferation is usually mild and not always obvious in routine sections; special studies have shown a quantitative increase.⁶⁸⁰ There is sometimes an increase in the number and size of hair follicles and sebaceous glands. There may be smooth muscle hypertrophy of the arrectores pilorum as well as smooth muscle bundles in the dermis that are not related to cutaneous adnexa.^{681,682} Controversy exists about the relationship of these cases to smooth muscle hamartoma (see p. 1033).^{683,684}

Electron microscopy

There is an increase in the number and size of melanosome complexes in the basal and prickle cells of the epidermis with an increase in the number of melanosomes in the complexes.⁶⁸⁵ There are also many single collagen fibrils in the dermis.

DOWLING–DEGOS DISEASE

Dowling–Degos disease (OMIM 179850), also known as reticulate pigmented anomaly of the flexures, is a rare autosomal dominant genodermatosis in which there are spotted and reticulate pigmented macules of the flexures.^{686,687} A loss-of-function mutation in the keratin 5 (*KRT5*) gene mapping to chromosome 12q13 (but assigned in one report to 17p13.3⁶⁸⁸) has been described in this disorder.^{689,690} In a report of generalized Dowling–Degos disease in a Chinese family, *POFUT1* mutations were found to be responsible; this gene encodes

Figure 10.12 Becker's nevus. (A) The epidermis shows mild papillomatosis and basal hyperpigmentation. (B) The bottom of some of the rete pegs is straight. (H&E)

Figure 10.13 Becker's nevus. In this example, the rete ridges have pointed tips. (H&E)

protein O-fucosyltransferase 1, involved in ligand-induced receptor signaling.⁶⁹¹ Whereas mutations affecting the early N-terminal domain of *KRT5* appear to be responsible for most cases of Dowling–Degos disease, similar mutations in *KRT14* produce Naegeli–Franceschetti–Jadassohn syndrome.^{690,692} Less constant features include pigmented pits in the perioral area, localization to the vulva^{693,694} or axillae,⁶⁹⁵ scattered comedo-like lesions,^{696,697} keratoacanthomas,⁶⁹⁸ squamous cell carcinomas,⁶⁹⁹ hidradenitis suppurativa,⁷⁰⁰ and seborrheic keratoses.^{686,701,702} The condition usually develops in early adult life and is slowly progressive.⁶⁸⁶ Patients with achromic macules and papules probably constitute a variant of Dowling–Degos disease.⁷⁰³ Such cases have some overlap features with dyschromatosis symmetrica hereditaria (see p. 334) and dyschromatosis universalis hereditaria.^{689,704} However, a recent case of Dowling–Degos disease with hypopigmented macules was found to have histopathologic changes consistent with that of disease and different from the two dyschromatosis syndromes (see later).⁷⁰⁵

It is now considered that Haber's disease,^{706,707} in which there are rosacea-like facies and seborrheic keratosis-like lesions, and **reticulate acropigmentation of Kitamura**,^{702,708–714} in which there are reticulate, slightly depressed, pigmented macules on the extensor surface of the hands and feet in association with palmar 'pits', are different phenotypic expressions of the same genodermatosis.^{715–721} Overlap features are sometimes present.^{722,723} However, studies using whole-exome sequencing have identified *ADAM10* mutations as a cause of reticulate acropigmentation of Kitamura, suggesting that this condition is distinct from Dowling–Degos disease.⁷²⁴ A further related entity, characterized by reticulate pigmentation on the face and neck and epidermal cysts on the trunk, has been reported.⁷²⁵

A further variant is **Galli–Galli disease**, in which patients display prominent acantholytic changes on histology, in addition to clinical and pathological features resembling those of Dowling–Degos disease.⁷²⁶ Two patients have been reported with erythematous scaly plaques and lentigo-like macules on the trunk and lower extremities, rather than the reticulate macules of the flexures as usually seen.⁷²⁷ Mutations in the *KRT5* gene, encoding one of the two major basal epidermal keratin intermediate filaments, have been described in Galli–Galli disease.⁶⁹² It remains to be determined whether the acantholysis is related to a specific mutation in this gene. Recent work has shown that the same *KRT5* mutation is found in patients with

Dowling–Degos disease and Galli–Galli disease (c.418dupA) and that acantholysis is present in a significant number of patients previously diagnosed with Dowling–Degos disease, supporting the impression that Galli–Galli disease is in fact a variant of Dowling–Degos disease rather than a distinct entity.⁷²⁸

Histopathology^{686,697}

There are filiform downgrowths of the epidermis and also of the variably dilated pilosebaceous follicles.^{686,729} Small horn cysts and comedo-like lesions are also present. Hyperpigmentation is quite pronounced at the tips of the rete ridges. In the hypopigmented macules, there were also filiform downgrowths of the epidermis; with Fontana–Masson staining, pigmentation was limited to the tips of rete ridges, with loss of pigment in the remainder of the basilar layer.⁷⁰⁵ As noted previously, in more than one patient with Dowling–Degos disease, biopsies show features of Galli–Galli disease with suprabasal lacunae.⁶⁸⁹ In Kitamura's disease, the appearances resemble those seen in a solar lentigo, with club-shaped elongations of the rete ridges but with intervening epidermal atrophy.^{716,730,731} Dopa-positive melanocytes are increased.⁷³² Desmocollin 3 was increased in the epidermal rete ridges in one case.⁷³³ Other features include melanin incontinence and a mild to moderate superficial perivascular infiltrate of lymphocytes. In Galli–Galli disease, there are digitate downgrowths of the rete ridges with basal hyperpigmentation. There are suprabasal acantholytic lacunae with a slightly parakeratotic roof but no significant dyskeratosis.⁷³⁴

A 'brown star' pattern on an erythematous background has been found on demoscropy in generalized Dowling–Degos disease.⁷³⁵

Electron microscopy

Melanosomes are markedly increased in keratinocytes, and these may be dispersed through the cytoplasm or loosely aggregated.^{736,737} They are of normal size. Melanocytes are increased in number in Kitamura's variant.⁷³¹ There are many melanosomes in melanocytes, keratinocytes, and melanophages.⁷³³

Differential diagnosis

The hypopigmented macules described in a recent case had the typical digitate epidermal downgrowths of Dowling–Degos disease but with pigmentation (as revealed by Fontana–Masson staining) limited to the tips of the digitate rete ridges. This is in contrast to the findings in hypopigmented lesions of dyschromatosis symmetrica hereditaria and dyschromatosis universalis hereditaria, in which there is simply reduced pigmentation in the epidermal basilar layer.⁷⁰⁵ There is a superficial resemblance to the adenoid form of seborrheic keratosis, although the downgrowths are more digitate than in seborrheic keratosis and there is no papillomatosis.

POSTINFLAMMATORY MELANOSIS

Hyperpigmentation may follow a number of inflammatory dermatoses, particularly those involving damage to the basal layer.⁷³⁸ Thus, it may follow various disorders that present a lichenoid reaction pattern, such as lichen planus, lichenoid drug eruptions, and fixed drug eruptions. Prominent hyperpigmentation is almost invariable in the resolving phases of a phytophotodermatitis (see p. 621). Sometimes pigmentation is labeled 'postinflammatory' but no etiology is apparent.⁷³⁹ Specific drugs that may cause postinflammatory and/or increased basal pigmentation include the following: prostaglandin analogues,⁷⁴⁰ IFN- α used for hepatitis C infection,⁷⁴¹ the antipsychotic drug olanzapine,⁷⁴² hydroxyurea,⁷⁴³ and calcipotriol.⁷⁴⁴

Figure 10.14 Postinflammatory melanosis. This lesion shows increased amounts of melanin in the basal layer, in addition to prominent melanin incontinence. (Fontana–Masson)

Histopathology

In addition to prominent melanin incontinence, there may be normal or increased amounts of melanin in the basal layer of the epidermis (Fig. 10.14). Basal pigmentation is prominent in phytophotodermatitis. The repigmentation observed in lichen sclerosus, following the use of topical tacrolimus, involved basal hyperpigmentation and not melanin incontinence.⁷⁴⁵ Stem cell factor may produce a similar change at injection sites.⁷⁴⁶ If basal pigmentation is markedly reduced, the clinical appearance will be of hypopigmentation. There may also be occasional lymphocytes around vessels in the papillary dermis and a mild increase in fibroblasts and even collagen in the papillary dermis. There is usually no evidence of the underlying dermatosis that resulted in the area of pigmentation.

PRURIGO PIGMENTOSA

Prurigo pigmentosa is a rare pruritic dermatosis of unknown etiology in which erythematous papules, characteristically on the back, neck, and chest, coalesce to form a reticulate pattern.⁷⁴⁷ Vesicular and bullous lesions have been reported.⁷⁴⁸ This stage resolves within days, leaving a mottled or reticulate hyperpigmentation.^{749–752} There is a female predominance. The average age of onset is between 23 and 27 years.⁷⁵³ More than 300 cases have been reported from Japan, leading to the suggestion that an environmental factor is responsible.⁷⁵⁴ It is uncommon in the Western world, although more than 50 cases have been reported.^{755–758} Ketosis has also been implicated.^{759–761} Its association with *Helicobacter* infection may have been fortuitous,⁷⁶² although in a recent case *H. pylori* organisms were identified in a skin biopsy of prurigo pigmentosa.⁷⁶³ A Korean study suggested a link between this disorder and fasting; half of the 16 patients in this study showed a chronological association between onset of pigmented lesions and fasting, and ketosis was found in 6 of the patients.⁷⁶⁴ Prurigo pigmentosa may be classed as a postinflammatory melanosis.⁷⁶⁵ Minocycline is usually first-line therapy.^{757,758,766} Doxycycline, macrolide antibiotics, isotretinoin,⁷⁶⁷ and dapsone have also been used to treat this condition.^{753,755,767} Narrowband UVB therapy was used successfully in one case.⁷⁶⁸

Figure 10.15 Prurigo pigmentosa. There are mild interface changes with some vacuolar change and apoptotic keratinocytes. (H&E)

Histopathology^{747,749–751,769,770}

Böer and Ackerman reviewed the features of 25 patients and another 178 patients recorded in the literature.^{747,770} They commented on the rapid course of lesions over a period of 1 week. In the initial phase, there is a superficial perivascular and interstitial infiltrate of neutrophils that are soon scattered through the papillary dermis and epidermis. This is followed by neutrophilic spongiosis and focal epidermal microabscesses, accompanied by ballooning and degeneration (both apoptotic and necrotic) of keratinocytes. This is soon followed by the influx of eosinophils and lymphocytes into the upper dermis. There may be focal lichenoid qualities (Fig. 10.15), whereas in other cases there is extraordinary vacuolar alteration at the dermoepidermal junction.⁷⁷⁰ The epidermis becomes variably hyperplastic, parakeratotic, and hyperpigmented. This microscopic description is basically in agreement with a study of 50 cases by Kim *et al.*, who found early dermatitis herpetiformis-like changes with progression to an impetigo-like or acute generalized exanthematous pustulosis-like image, followed by postinflammatory hyperpigmentation.⁷⁷¹

In the late stages, there is prominent melanin incontinence with numerous melanophages in the dermis.

GENERALIZED MELANOSIS IN MALIGNANT MELANOMA

Cutaneous pigmentation that is slate gray or bluish black in color may rarely develop in patients with disseminated malignant melanoma.^{772,773} Although generalized, the pigmentation is often accentuated in areas exposed to the light.

The pathogenesis of the pigmentation is controversial.⁷⁷³ It has been attributed to epidermal hyperpigmentation, the deposition of melanophages that have circulated in the blood, the presence of scattered melanoma cells within the dermis,⁷⁷⁴ and the regression of dermal tumor cells (see p. 888).

Histopathology⁷⁷³

The usual finding is the presence of melanin pigment throughout the dermis in perivascular and interstitial melanophages and as free granules. A scant perivascular infiltrate of lymphocytes and sometimes plasma cells may be present. Individual melanoma cells are not usually present.

DERMATOPATHIA PIGMENTOSA RETICULARIS

Dermatopathia pigmentosa reticularis (OMIM 125595) combines generalized reticulate pigmentation with nail dystrophy and partial alopecia.^{775–778} Macules of hypopigmentation may develop at a later stage. Other reported findings include the absence of dermatoglyphics, hypohidrosis or hyperhidrosis, hyperkeratosis of palms and soles, and nonscarring acral blisters.⁷⁷⁹ There are similarities to the Naegeli–Franceschetti–Jadassohn syndrome, with which it is allelic, although the associated features are different.⁷⁸⁰ Both conditions are autosomal dominant due to mutations in the keratin-14 (*KRT14*) gene on chromosome 17q12–q21.⁷⁸⁰

Histopathology

The hyperpigmented areas show conspicuous melanin incontinence.^{775,778} The epidermis appears normal. Another reported case showed basal layer degeneration, dermal melanophages, and an absence of appendages.⁷⁷⁸

NAEGELI–FRANCESCHETTI–JADASSOHN SYNDROME

Naegeli–Franceschetti–Jadassohn syndrome (Naegeli syndrome; OMIM 161000) is an extremely rare, autosomal dominant ectodermal dysplasia combining dark brown, reticulate pigmentation of the trunk and limbs with diffuse or punctate hyperkeratosis of the palms and soles.^{781,782} Hypohidrosis, enamel hypoplasia, and nail dystrophy may also be present. Incomplete forms or variations have been reported,^{783,784} the term ‘hereditary diffuse hyperpigmentation’ was used for one such case.⁷⁸⁵ The gene for this syndrome, the keratin-14 (*KRT14*) gene, maps to chromosome 17q11.2–q21 (also given as 17q12–q21).^{780,786} As such, it is allelic to dermatopathia pigmentosa reticularis.⁷⁸⁰

This genodermatosis is one of the many that may present with reticulate, patchy, and mottled pigmentation of the neck. A review of all such dermatoses, congenital and acquired, was published in 1998.^{787,788}

Histopathology

Melanin is increased in the basal layers of the epidermis, and there is prominent melanin incontinence.⁷⁸¹

Numerous milia were present in one case.⁷⁸⁴

INCONTINENTIA PIGMENTI

Incontinentia pigmenti (OMIM 308300) is an uncommon, multisystem genodermatosis with cutaneous, skeletal, ocular, neurological, dental, and other abnormalities.^{789–792} The ocular and neurological changes are sometimes the dominant clinical features of the disorder.^{793–797} The cutaneous lesions evolve through vesiculobullous, verrucous, and pigmentary stages, but in a small number of individuals pigmentation is the first manifestation. This occurs when there is reduced expression of the phenotype.⁷⁹⁸ The vesiculobullous lesions, accompanied by erythematous areas, are present at birth or soon after in a linear arrangement on the extremities and lateral aspects of the trunk. Skin lesions tend to be patterned along Blaschko’s lines.⁷⁹⁶

Rarely, they are papular in type.⁷⁹⁹ Vesicular recurrences, later in life, are rare.^{800–803} The verrucous lesions evolve some weeks or months later and resolve spontaneously to give atrophy, depigmentation, or both. In the third stage, which has a peak onset at approximately 3–6 months, there are streaks and whorls of brown to slate gray pigmentation, often asymmetrically distributed on the trunk and sometimes on the extremities.^{790,804} The pigmentation, which is not necessarily in areas of the earlier lesions, progressively fades at approximately puberty. Areas of hyperpigmentation, sometimes associated with verrucous plaques, may remain.⁸⁰⁵ Uncommonly, streaks of hypopigmentation are the predominant feature,^{806–809} they are usually found in adulthood but may develop earlier.^{810,811}

Other cutaneous manifestations include alopecia, rarely of a whorled scarring type,⁸¹² woolly hair nevus,⁸¹³ nail dystrophy,^{814,815} and painful subungual tumors that may involve several fingers and sometimes toes.^{816,817} These keratotic tumors have an onset in late adolescence and may involute spontaneously.^{818,819} Several cases of incontinentia pigmenti have been associated with cancer in childhood.⁸²⁰ One case was associated with neonatal herpes simplex infection.⁸²¹ Peripheral eosinophilia is often present.⁸²²

Incontinentia pigmenti is a chromosomal instability disorder that is inherited as an X-linked dominant gene that usually causes the death *in utero* of affected males.^{808,813,820,823} Heterozygous females survive due to functional mosaicism.⁸²⁴ Two gene loci have been identified for this disease – Xp11.21 and Xq28⁸⁰⁰ – although some studies and OMIM list only Xq28.⁸²⁵ Mutations in the IKK- γ gene (*IKBK*G), also called *NEMO*, which maps to Xq28, cause incontinentia pigmenti. The *NEMO/IKBK*G gene controls the nuclear factor- κ B (NF- κ B) signaling pathway, which controls various cytokines and chemokines, and protects cells against apoptosis.^{826,827} In the dermatological literature, *NEMO* (nuclear factor- κ B essential modulator) is the preferred designation for this gene.^{824,828,829} Loss-of-function mutation of *NEMO* accounts for 80% of cases. Hypomorphic mutations of *NEMO* result in incontinentia pigmenti in heterozygous females and in hypohidrotic ectodermal dysplasia associated with severe immunodeficiency (OMIM 300291) that is allelic.⁸²⁴ The small number of males (now approximately 50) reported with the condition^{822,825,830} may represent genetic heterogeneity mutations, although several cases have shown mosaicism for a deletion of the *NEMO* gene.^{790,824,825} In one boy, XXY mosaicism was present,⁸³¹ another patient had Klinefelter's syndrome.⁸³² Father-to-daughter transmission has been recorded.⁸³³

Several patients have had defects in neutrophil chemotaxis and lymphocyte function.^{834–837} Leukotriene B₄ has been demonstrated in extracts of the crusted scales from vesiculobullous lesions, and this may have an important role in the chemotaxis of eosinophils into the epidermis.⁸³⁸ More important is the activation of eotaxin, a direct consequence of the genetic mutation, which is a potent eosinophil-selective chemokine. It is increased in the skin during the vesiculobullous stage.⁷⁹³

It has been postulated that the manifestations of incontinentia pigmenti can be explained as an autoimmune attack on ectodermal clones expressing an abnormal surface antigen⁸³⁹ or as premature (programmed) cell death in defective ectodermal clones.⁸⁴⁰ Apoptosis is increased as a direct consequence of the mutation.

Histopathology

The first stage of incontinentia pigmenti is characterized by eosinophilic spongiosis – that is, spongiosis progressing to intraepidermal vesicle formation with prominent exocytosis of eosinophils into and around them (Fig. 10.16). A few basophils are also present.⁸⁴¹ The erythematous areas show only minimal spongiosis, but there is still prominent exocytosis of eosinophils. There are occasional dyskeratotic cells with eosinophilic hyaline cytoplasm in the epidermis adjacent to the

Figure 10.16 Incontinentia pigmenti (first stage). Numerous eosinophils extend into the epidermis. Spongiosis is mild in this field. (H&E)

Figure 10.17 Incontinentia pigmenti (verrucous stage). There are many dyskeratotic cells within the epidermis. (H&E)

vesicles.⁸¹³ The superficial dermis contains an infiltrate of eosinophils and some mononuclear cells. Eosinophil granule major basic protein is also present.⁸⁴²

In the verrucous stage, there are hyperkeratosis, acanthosis, mild irregular papillomatosis, and numerous dyskeratotic cells (Fig. 10.17). Some macrophages migrate into the epidermis; on electron microscopy, these have been shown to phagocytose the dyskeratotic cells as well as melanosomes. Inflammatory cells are quite sparse. In the third stage, there is pronounced melanin incontinence (Fig. 10.18). Pale scarred areas may be found on the lower part of the legs; these show a reduction in the number of melanocytes and some increase in dermal collagen.⁸⁴³

The subungual lesions show hyperkeratosis, verrucous or pseudoepitheliomatous hyperplasia, and dyskeratotic cells at all levels of the epidermis.^{816,818,819} Neighboring keratinocytes may form whorls around the dyskeratotic cells.

Electron microscopy

On electron microscopy, some of the dyskeratotic cells have masses of loosely arranged tonofilaments, although most have clumped,

Figure 10.18 Incontinentia pigmenti (third stage). Melanin incontinence is apparent. Note that there are also a few remnant dyskeratotic cells at the epidermal surface (arrows). (H&E)

electron-dense tonofilaments.⁸⁴⁴ Pigment incontinence appears to result from phagocytosis of melanosomes by macrophages.^{845,846} In one family of patients with incontinentia pigmenti, there were structural abnormalities of leukocytes including hypogranular granulocytes, 'pseudoplatelets' (budding of surface cytoplasm), and nuclear anomalies that included radially segmented nuclei and perichromatin granules.⁸⁴⁷

RETICULATE PIGMENTARY DISORDER WITH SYSTEMIC MANIFESTATIONS

This X-linked disorder (OMIM 301220) is characterized by cutaneous pigmentation mimicking incontinentia pigmenti, associated with failure to thrive, chronic pulmonary disease, hypohidrosis, and coarse hair.⁸⁴⁸ The gene maps to Xp21 near the dystrophin locus.⁸⁴⁸ Although amyloid was found in the papillary dermis of the original case, it has not been found in subsequent cases. At one point, this condition was called familial cutaneous amyloidosis.⁸⁴⁸ Female carriers have cutaneous manifestations similar to third-stage incontinentia pigmenti but without cutaneous atrophy or systemic manifestations.⁸⁴⁹

Histopathology

Affected skin shows mild hyperkeratosis, basal hyperpigmentation, and numerous dermal melanophages. Occasional apoptotic keratinocytes are also present.⁸⁴⁸ No amyloid has been present, other than in the original report.

FRICTIONAL MELANOSIS

Localized hyperpigmentation may develop at sites of chronic friction.^{850,851} This condition must be distinguished from macular amyloidosis, which clinically it resembles. Frictional melanosis usually occurs over bony prominences, following prolonged and repetitive friction. In some countries, the use of a scrub pad (loofah) has been implicated.⁸⁵² It is more common in patients who have skin phototype III–V.⁸⁵³ Lactic acid peel has been found to be an effective treatment for this disorder.⁸⁵⁴

Sock-line hyperpigmentation is a related condition due to trauma from the elastic bands often present in the upper portion of socks.^{855,856}

Figure 10.19 Notalgia paresthetica. There are numerous melanophages, particularly around vessels in the superficial plexus. No amyloid was present. (H&E)

It has also been likened to amniotic bands of infancy. 'Heel-line' hyperpigmentation is a curvilinear pigmentation seen in infants wearing heel-length socks;⁸⁵⁷ a similar pigmentation due to tight-fitting mittens has been termed 'mitten-line' hyperpigmentation.⁸⁵⁸

Histopathology

A prominent feature is the presence in the upper dermis of melanin, most of which is contained in melanophages.⁸⁵⁰ Vacuolar change and scattered degenerate keratinocytes have also been noted in some cases.⁸⁵⁰

NOTALGIA PARESTHETICA

Notalgia paresthetica is a sensory neuropathy involving the posterior primary rami of thoracic nerves T2–T6 and presenting as a localized area of pruritus of the back.^{859–861} The affected region is sometimes lightly pigmented and composed of groups of small tan macules. Similar cases have been reported in the literature as 'peculiar spotty pigmentation'⁸⁶² and 'idiopathic pigmentation of the upper back'.⁸⁶³ Clinically, notalgia paresthetica resembles macular amyloidosis, a condition that in one report required ultrastructural examination to confirm the presence of amyloid because histochemical tests were negative.⁸⁶⁴

The symptoms may result from an increase in sensory epidermal innervation in affected skin.⁸⁶⁵ More likely is the role played by degenerative changes in the spine, leading to spinal nerve impingement.^{866,867} In one series of 43 patients, 60.7% had spinal changes deemed to be relevant.⁸⁶⁸

Treatment with botulinum toxin type A, by intradermal injections, was successful in one small series of two patients.⁸⁶⁹ Successful treatment has also been reported with amitriptyline.⁸⁷⁰

Histopathology

There is melanin pigment in macrophages in the upper dermis, sometimes accompanied by mild hyperpigmentation of the basal layer (Fig. 10.19).^{863,871} The pattern is that of mild postinflammatory pigmentation. In several reported cases, scattered degenerate keratinocytes were present within the epidermis.^{859,865} Although no amyloid was seen in two combined series of 24 cases, it is often present.^{867,872} It is possible

that amyloid forms in chronic lesions as a consequence of prolonged scratching.

Immunohistochemistry with neural and neuropeptide markers did not reveal a significant difference between lesional skin and nonlesional skin.⁸⁷²

‘RIPPLE’ PIGMENTATION OF THE NECK

Although ‘ripple’ pigmentation is usually regarded as a feature of macular amyloidosis, it has also been described on the neck in almost 2% of individuals with atopic dermatitis of long standing.^{873,874}

Histopathology

The most prominent feature is the presence of melanin in the upper dermis, both free and in macrophages.⁸⁷³ An increase in melanocytes with associated mild vacuolar change in the basal layer has been an inconstant feature.⁸⁷⁴

‘TERRA FIRMA-FORME’ DERMATOSIS

‘Terra firma-forme’ dermatosis is a relatively common condition that usually affects the neck of children. It has also been reported as dermatitis neglecta (see p. 612). It has the appearance of a dirty brown

mark that cannot be washed off with soap but is easily removed with alcohol.^{875–877} It can often be mistaken for acanthosis nigricans and other conditions. It appears to be caused by disordered keratinization.

Histopathology

There is mild acanthosis and orthokeratosis with numerous keratin globules, or whorls, in the stratum corneum. In a recent case, Dalton and Pride described orthohyperkeratosis, papillomatosis, and acanthosis; keratin whorls were not noted.⁸⁷⁸ However, in their response to a letter to the editor regarding their case, Dalton, Lountzis, and Pride described another case they had observed in which keratin whorls were found.⁸⁷⁹

Differential diagnosis

In the absence of keratin whorls, the described histopathologic findings could be difficult to distinguish from acanthosis nigricans, epidermal nevi, or particularly confluent and reticulated papillomatosis.⁸⁸⁰ Further studies may be necessary to determine whether keratin whorls can be used as a reliable differentiating feature.

Acro-osteolysis	360	Focal facial dermal dysplasia	371		
Chemical- and drug-related disorders	360	Pseudoainhum constricting bands	372		

INTRODUCTION

Collagen is the major structural constituent of mammalian connective tissues.¹ It accounts for well over 70% of the dry weight of the skin.² There are at least 10 genetically distinct types of collagen, and it is the relative content of these different collagen types, as well as the amount of elastic tissue and nonstructural constituents such as the proteoglycans, that determines the specific biomechanical properties of the various connective tissues.^{3,4}

Normal collagen

Before discussing the disorders of collagen in the skin, a brief account is given of the composition, types, and metabolism of collagen.

Composition of collagen¹

The structural collagens – types I, II, and III – are composed of three polypeptide chains, called alpha (α) chains, each of which contains approximately 1000 amino acid residues, one-third of which are glycine. Proline and hydroxyproline are other important amino acids, constituting up to 20% of the amino acids. The sequence and composition of amino acids differ in the α chains of the various collagens.⁴ Each of the α chains is coiled in a helix, and the three chains which together constitute a collagen molecule are in turn coiled on each other to form a triple helical structure. Short nonhelical extensions are found at both ends of the molecule at the time it is secreted into the tissues. These extensions are soon cleaved from the procollagen molecules by two different proteases. This produces a shorter molecule that, by lateral and longitudinal association with others, produces collagen fibrils. At the same time, oxidation of lysyl and hydroxylysine residues results in the formation of stable cross-links that give tensile strength to the collagen.

Types of collagen³⁻⁶

As mentioned previously, at least 10 genetically distinct collagens have been characterized, and at least 20 distinct genes encode the subunits of the various types of collagen.⁷ Two of the three structural collagens, types I and III, are important constituents of the skin, whereas type IV collagen is an important constituent of the basement membrane (see p. 155). Only small amounts of the other collagen types are found in the skin.³

Type I collagen is the most abundant collagen in the dermis.³ It comprises about 80% of dermal collagen and plays a major role in providing tensile strength to skin.⁸ It is composed of two identical alpha chains and a third chain of different amino acid composition. The genes for these different chains are thought to be on chromosomes 17 and 7 respectively.

Type III collagen constitutes approximately 50% of fetal skin but less than 20% of adult skin.² It is also present in internal organs. This collagen type is composed of three identical α chains. Type III collagen is believed to accommodate the expansion and contraction of tissues such as blood vessels and viscera.⁹ Reticulin fibers may represent type III collagen. The synthesis of type III collagen is controlled by the COL3A1 gene on chromosome 2q31–q32.

Type IV collagen has a honeycomb or reticular pattern in contrast to the fibrillar pattern of the other major collagen types.^{10,11} It is an important constituent of the lamina densa of the basement membrane.^{10,11} Type V collagen is a low-abundance fibrillar collagen that is coexpressed with collagen I in many tissues and forms with it heterotypic fibrils.¹² Collagen V appears to play a crucial role in the assembly of these heterotypic fibers and in regulating their diameter.¹² An abnormality has been found in some patients with Ehlers–Danlos syndrome type I. Type VII collagen is found in the sublamina densa region of the basement membrane zone forming the anchoring filaments (see

p. 156). Type XVI collagen, a member of the fibril-associated collagens with interrupted triple helices, localizes preferentially in the papillary dermis. It is also found in some sclerotic processes, such as scleroderma.¹³ Type XVII collagen is the bullous pemphigoid antigen.

Metabolism of collagen

The metabolism of collagen is a complex process involving a balance between its synthesis and its degradation.¹⁴ There are numerous steps involved in the synthesis of collagen, and the regulatory mechanisms are not fully understood. Procollagen is formed in the rough endoplasmic reticulum of fibroblasts. After passing through the Golgi apparatus, it is transported to the cell surface and secreted into the interstitium of the connective tissue.¹⁴ Here occur cleavage of the terminal extensions of procollagen and the subsequent cross-linking of molecules to form stable collagen.¹⁵ Collagen appears to be turned over continuously; its degradation is brought about by collagenase. It is remarkably resistant to proteolysis by most tissue proteinases.¹⁴

Various substances can interfere with the synthesis of collagen. The most important are the corticosteroids, which appear to act at several levels in the biosynthetic pathway.¹⁵

Categorization of collagen disorders

Although the various disorders of connective tissue have been assigned to a particular chapter of this volume on the basis of which element is most affected, it must be emphasized that an alteration in one component of connective tissue may influence the synthesis, deposition, and structure of other components.¹⁶ For instance, alterations in the elastic tissue and proteoglycan composition of the dermis may be found in some of the primary disorders of collagen.

The following categories are considered, although it is acknowledged that the allocation of some of the disorders to a particular section is somewhat arbitrary:

- Scleroderma
- Sclerodermoid disorders
- Other hypertrophic collagenoses
- Atrophic collagenoses
- Perforating collagenoses
- Variable collagen changes
- Syndromes of premature aging.

Note that diseases such as systemic lupus erythematosus and polyarteritis nodosa, which have been regarded in the past as ‘collagen diseases’, are not included in this chapter because they are not disorders of collagen in the strict sense. They are discussed with their appropriate tissue reaction pattern.

SCLERODERMA

The term ‘scleroderma’ refers to a group of diseases in which there is deposition of collagen in the skin and sometimes other organs as well. It may occur as a localized cutaneous disease in which the disorder of connective tissue is limited to the skin and sometimes structures beneath the affected skin, or it may occur as a systemic disease in which cutaneous lesions are accompanied by Raynaud’s phenomenon and variable involvement of other organs.¹⁷⁻²⁰

This classification of scleroderma is used in the account that follows:

1. Localized scleroderma
 - Morphea and variants
 - Linear scleroderma
2. Systemic scleroderma
 - Diffuse form (progressive systemic sclerosis)
 - Limited form (includes acrosclerosis and the ‘CREST’ syndrome)

3. Mixed connective tissue disease
4. Eosinophilic fasciitis
5. Atrophoderma (of Pasini and Pierini).

LOCALIZED SCLERODERMA

Localized scleroderma is the most common form of scleroderma.²¹ It generally occurs in children and young adults, and there is a female preponderance.^{22,23} Neonatal onset has been recorded.²⁴ There is no visceral involvement or Raynaud's phenomenon, and it usually has a self-limiting course. Progression to or coexistence of the systemic form is rare.^{22,25} Antinuclear antibodies are uncommon except in the linear form.²⁶

Morphea

Morphea is the most common form of scleroderma. Usually it presents on the trunk or extremities as one or several indurated plaques with an ivory center and a violaceous border (the 'lilac ring'). Lesions confined to the breast have been reported.²⁷ This can be accompanied by erythema, and it may be clinically mistaken for inflammatory carcinoma of the breast.²⁸ Irregular areas of hyperpigmentation or hypopigmentation may be present within the lesion.²⁹ Other clinical forms include guttate, generalized, subcutaneous, keloidal, and bullous types.^{22,30–32} Occasionally, more than one type is present in the same individual. An isolated lesion of oral mucosal morphea has been reported.³³

Guttate morphea consists of small, pale, slightly indurated lesions on the upper part of the trunk that may resemble lichen sclerosis et atrophicus.³⁴ In the rare *generalized morphea*, there are large plaque-like lesions, often with vague symmetry, involving the trunk and extremities.³⁵ Atrophy and fibrosis of the deep tissues may lead to crippling deformities. Ulceration and calcification may also develop in some of the lesions.³⁴ *Disabling pansclerotic morphea* is an aggressive variant of the generalized type and is of early onset.^{36,37} Lesions may develop in adult life.^{38,39} Lesions may extend circumferentially on an extremity leading to massive pansclerosis and atrophy.^{34,40} Peripheral eosinophilia and mild nonprogressive visceral changes are sometimes present in this variant.³⁷ Cutaneous squamous cell carcinoma (SCC) is a rare complication of long-standing lesions.^{41,42} *Subcutaneous (deep) morphea* (morphea profunda) consists of one or more ill-defined, deep sclerotic plaques on the abdomen, sacral area, or extremities; its progression is slow and usually relentless.^{43–47} Solitary lesions may not progress.⁴⁸ Rarely, the lesions have a linear arrangement.⁴⁹ Deep morphea has developed at the site of a previous vaccination.⁵⁰ *Keloidal (nodular) morphea* may be part of this spectrum, although the nodules may also be in the dermis, clinically resembling a keloid.^{22,51–54} Nodules are a rare finding in systemic and linear scleroderma.^{55–60} *Bullous lesions* may rarely complicate both localized and systemic scleroderma.^{30,61} They may present initially as acquired unilateral edema.⁶² In some cases, bullous morphea represents the secondary appearance of bullous lichen sclerosis et atrophicus on a lesion of morphea.^{63,64} *Superficial morphea* is a recently described variant that differs in its clinical and histological presentation from classic morphea.⁶⁵ There is minimal to no induration of patches that are hypo- or hyperpigmented.⁶⁵ Males are uncommonly affected.⁶⁶ There are no associated symptoms. It has been suggested that superficial morphea is atrophoderma of Pasini-Pierini.^{67,68}

Coexistence of morphea and lichen sclerosis is reported (but see pp. 352 and 361),⁶⁹ and there are isolated reports of localized sclerodermatous lesions occurring in association with elastosis perforans serpiginosa ('perforating morphea'),⁷⁰ granuloma annulare,⁷¹ Hashimoto's thyroiditis,⁷² multiple myeloma,⁷³ a herpes zoster scar,⁷⁴ xanthomatosis,⁷⁵ a congenital hypopigmented plaque of unknown type,⁷⁶ discoid

lupus erythematosus,⁷⁷ subacute lupus erythematosus,⁷⁸ and the presence of the so-called 'lupus anticoagulant' (see p. 225).⁷⁹ Generalized morphea has been reported in a patient with Felty's syndrome.⁸⁰ Bronchiolitis obliterans developed in another patient.⁸¹

The etiology of morphea is controversial. Antibodies and lymphoproliferative responses⁸² to *Borrelia burgdorferi*, the cause of Lyme disease, have been detected in a significant number of patients with morphea in Austria and some other areas of Europe.^{83–85} Spirochetes have been demonstrated in tissue sections in some cases using a modified silver stain,⁸⁶ an avidin-biotin immunoperoxidase system,^{87,88} or techniques using the polymerase chain reaction (PCR).^{89,90} Organisms have also been detected by focus-floating microscopy.⁹¹ An association of morphea with acrodermitis chronica atrophicans, a known manifestation of Lyme borreliosis, has also been reported.⁹² However, these findings have not been confirmed in most other countries,^{93–95} and this leads to the view that in most instances there is no association between *B. burgdorferi* infection and morphea.^{96–102} Another explanation is that certain genotypes of *Borrelia* found only in areas of Europe and Japan are responsible, as is the situation with lichen sclerosis et atrophicus.¹⁰³ However, this explanation was not confirmed by a study from Germany that found no evidence of *Borrelia* by PCR in lesional skin of 33 patients with morphea.¹⁰⁴ It has also been suggested that a new spirochetal agent unrelated to *B. burgdorferi* may be the causative agent in some countries.¹⁰⁵ The increased collagen synthesis by fibroblasts in morphea may result from lymphokines released by the inflammatory cell infiltrate.¹⁰⁶ Transforming growth factor- β (TGF- β) is increased in lesional skin.¹⁰⁷ Serum levels of procollagen type I carboxy-terminal propeptide are increased in patients with localized and systemic scleroderma.¹⁰⁸ Insulin-like growth factor (IGF)-I, which is a profibrotic compound, is increased in lesional and nonlesional skin of patients with morphea.¹⁰⁹ Features of autoimmunity are also present in localized scleroderma, with a high percentage of patients having antinucleosome and antihistone antibodies.^{110–113} Anti-agalactosyl antibodies are present in approximately 20% of patients, and they can be an indicator of disease severity.¹¹⁴ Antinuclear antibodies are uncommon except in the linear form;²⁶ antibodies to single-stranded DNA are sometimes present, particularly in generalized morphea.^{115,116} Rheumatoid factor is present in approximately 20% of cases.^{117,118} Increased levels of circulating ICAM-1 are present; the levels correlate with the number of lesions and the area involved.¹¹⁹ Whereas TGF- β is known as a profibrotic cytokine that may have a role in the pathogenesis of scleroderma, decorin reduces TGF- β levels and has antifibrotic properties. Decorin levels are increased in the early stages of scleroderma, particularly the systemic form.¹²⁰ There has been recent interest in the role of a phenomenon called epithelial-mesenchymal transition (EMT) in the sclerosing process of morphea – a phenomenon that may participate in fibrosing processes in other organ systems such as lung and liver. In this process, epithelial cells lose their properties and take on mesenchymal cell characteristics. TGF- β stimulation brings about expression of the transcription factor Snail in epithelial cells. Snail in turn inhibits and reduces E-cadherin expression, conferring upon these cells increased migratory capacity and expression of fibronectin.¹²¹ There is preliminary evidence that this phenomenon does occur in the skin of patients with morphea.¹²¹

Morphea has developed, in a few instances, at the site of previous radiotherapy (radiation port scleroderma).^{122–126} There is a marked upregulation of collagen synthesis following radiotherapy.¹²⁷ Synchronous development of angiosarcoma, melanoma, and morphea of the breast was reported to have occurred 14 years following radiotherapy for breast carcinoma.¹²⁸ Morphea has also been reported in a patient taking the semisynthetic ergot alkaloid bromocriptine, a drug that has been associated with pulmonary fibrosis.¹²⁹ It has followed the use of balicatib, a cathepsin K inhibitor,¹³⁰ and hepatitis B vaccination in an infant.¹³¹ It has also developed adjacent to the site of a leaking silicone-gel breast implant,¹³² as a tattoo reaction,¹³³ and in areas of chronic

venous insufficiency.¹³⁴ Other possible triggers of morphea include treatments with tumor necrosis factor- α ,^{135,136} adalimumab given for ankylosing spondylitis,¹³⁷ and the cathepsin K inhibitor balicatib (described as morphea-like skin reactions).¹³⁸

Therapies have included PUVA-related protocols,^{139,140} sometimes with oral retinoids,¹⁴¹ UVA1 phototherapy,^{142,143} which has been used in low dose with calcipotriol ointment;¹⁴⁴ calcipotriol with corticosteroids;¹⁴⁵ photodynamic therapy;¹⁴⁶ corticosteroids for localized lesions;¹⁴⁷ pulsed high-dose corticosteroid, with low-dose methotrexate;^{148,149} and systemic immunosuppression and PUVA therapy.¹⁵⁰ Newer treatments that have been reported include infliximab in generalized morphea,¹⁵¹ imatinib,¹⁵² imiquimod 5% cream,¹⁵³ abatacept in disseminated morphea profunda,¹⁵⁴ and tacrolimus ointment.¹⁵⁵ In a systematic review of treatments for this disease, phototherapy, methotrexate/systemic corticosteroids, calcipotriene, and topical tacrolimus were found to be the most efficacious.¹⁵⁶

Linear scleroderma

Linear scleroderma is a variant of localized scleroderma in which sclerotic areas of skin develop in a linear pattern.^{157,158} It is the second most common form of localized scleroderma after morphea.¹⁵⁹ It may occur on the head, trunk, or extremities; on the limbs it may extend the full length, leading to contractures of the joints that it crosses.¹⁶⁰ Muscle calcification is extremely rare.¹⁶¹ A familial case has been recorded.¹⁶²

Linear scleroderma involving the frontoparietal area is referred to as *en coup de sabre* from its supposed likeness to the scar of a saber cut.^{163–167} Central nervous system and ophthalmic involvement are rare.¹⁶⁸ An association with ipsilateral brain cavernomas (basically, cavernous vascular malformation) has been reported.¹⁶⁹ This variant, which is more likely to be bilateral than the other forms of linear scleroderma,^{170,171} may be associated with various degrees of facial hemiatrophy (Parry–Romberg syndrome).^{172–174} A study from Mexico City in 2002 found that it was possible to distinguish scleroderma *en coup de sabre* (SCS) from progressive facial hemiatrophy (Parry–Romberg syndrome).¹⁷⁵ Whereas cutaneous sclerosis was present in 8 of 13 patients with SCS, it was absent in all 9 patients with facial hemiatrophy. Cutaneous hyperpigmentation and alopecia were also more common in patients with SCS.^{175,176} The more frequent clinical features in facial hemiatrophy were total hemifacial involvement and ocular changes.¹⁷⁵ A retrospective study of 54 patients from the Mayo Clinic, reported in 2007, found 26 patients with SCS, 13 with Parry–Romberg syndrome, and 15 with both diseases. Bilateral disease was present in 4 patients. In addition to the association between this syndrome and SCS,^{177,178} other associations of Parry–Romberg syndrome have included borreliosis,¹⁷⁹ anti-double-stranded DNA antibodies,¹⁸⁰ and neurological involvement.¹⁷⁷ Rarely, linear scleroderma has been observed overlying the sclerosing bone dystrophy known as melorheostosis^{181–183} or in association with hypertrichosis^{184,185} or systemic lupus erythematosus.¹⁸⁶ Osteolysis with subsequent fractures is a rare occurrence.¹⁸⁷ In many cases, the lesions appear to have followed Blaschko's lines.^{60,188–190} The simultaneous occurrence of linear scleroderma and homolateral segmental vitiligo has been reported.¹⁹¹

The onset of linear scleroderma is sometimes abrupt and occasionally follows trauma.¹⁵⁷ Its mean duration is longer than that of plaque-type morphea, and it is less likely to resolve as completely. Disease activity is mirrored by the titer of antihistone autoantibodies, which decrease with disease resolution.¹⁹²

Topical calcipotriol, combined with PUVA therapy, has been used to treat SCS.¹⁶⁷ UVA1 phototherapy can also be used for various sclerotic skin diseases.¹⁹³

Histopathology²²

Localized scleroderma is characterized by three outstanding features – the deposition of collagen in the dermis and subcutis; vascular

changes; and an inflammatory cell infiltrate, particularly in early lesions.¹⁹⁴ These changes are now considered in detail. The epidermis may be normal, somewhat atrophic, or even slightly thicker than usual.¹⁹⁵

The dermis is increased in thickness and composed of broad sclerotic collagen bundles that stain strongly with the trichrome stain. Collagen also replaces the fat around the sweat glands and extends into the subcutis. In the latter site, the collagen is homogenized and less compact than in the dermis (Fig. 11.1), and it shows only weak birefringence and trichrome staining;¹⁹⁶ there is an increased number of fibroblasts. However, the collagen in the subcutis stains strongly with the PAS stain, in contrast to the very weak staining of that in the dermis. Mucopolysaccharides are present in the early lesions, particularly in the subcutis. Rarely, a secondary cutaneous mucinosis, with significant interstitial mucin, is present. In most cases of morphea, the thickened collagen bundles are in the mid and deep reticular dermis.

There is atrophy of adnexal structures, particularly the pilosebaceous units. Eccrine glands are situated at a relatively high level in the dermis as a result of the collagen deposited below them (Fig. 11.2). The

Figure 11.1 Localized scleroderma (morphea). The recently deposited collagen stains weakly with the usual collagen stains and is devoid of elastic tissue. (Verhoeff–van Gieson)

Figure 11.2 (A) Localized scleroderma (morphea). (B) Note the swollen collagen bundles, the atrophic sweat glands, and the straight edge of the dermal-subcutaneous interface. (H&E)

arrectores pilorum are often hypertrophied. The mesenchymal elements of peripheral nerves are involved in the sclerotic process.¹⁹⁷

The vascular changes are thickening of the walls of small blood vessels and narrowing of their lumen. In small arteries, there is fibromucinous thickening of the intima.

The inflammatory cell infiltrate is composed of lymphocytes with some macrophages and plasma cells. It is distributed around blood vessels or more diffusely through the lower dermis and subcutis, particularly at the border of early lesions. The infiltrate is more marked in localized scleroderma than in systemic scleroderma and in early rather than late lesions. The infiltrate is rarely heavy.¹⁹⁸ Immunohistochemical characterization of the infiltrate has shown the presence of T lymphocytes of both CD4 and CD8 subtype, as well as Langerhans cells and natural killer cells.¹⁹⁹

In *guttate* lesions, the changes are more superficial with less collagen sclerosis but with subepidermal edema, resembling this feature of lichen sclerosus et atrophicus. Linear lesions may show a deeper and more diffuse inflammatory cell infiltrate extending into the underlying muscle. In addition to the dermal sclerosis, collagenous replacement of subcutaneous fat, and eccrine atrophy expected in morphea, horizontal and vertical sections from alopecic areas in en-

coup de sabre linear morphea (SCS) show distinctive atrophic follicular structures resembling telogen follicles but with a lack of terminal hair differentiation.²⁰⁰

Vascular changes are usually prominent. Ossification of the dermis has been recorded.²⁰¹ The inflammation in the subcutis is also marked in the *generalized form*²⁰² and in subcutaneous morphea; in both, there may be marked fibrosis in the subcutis.³⁴

In *subcutaneous morphea*, there is thickening and hyalinization of collagen in the deep dermis and in the septa and fascia.²⁰³⁻²⁰⁵ There is a mixed inflammatory cell infiltrate that includes some multinucleate giant cells. Lipomembranous (membranocystic) changes may be present. Some confusion has arisen because of the variable use of the term 'subcutaneous morphea'. One group has suggested that the term 'morphea profunda' be used as an all-embracing one to include cases with dermal, subcutaneous, and fascial involvement, whereas 'subcutaneous morphea' should be used for cases in which the subcutaneous fat is mainly affected.²⁰³ According to this concept, eosinophilic fasciitis refers to the fascial component of morphea profunda.²⁰³ The concept has not gained wide acceptance.

In *keloidal nodules*, there are hyalinized thick collagen bundles associated with an increase in fibroblasts and mucin.⁵⁵ *Bullous lesions*

show subepidermal edema with dilated lymphatics in the underlying dermis.^{30,203,206} Erythrocytes are often present in the blister.²⁰⁶

In *superficial morphea*, the collagen deposition and inflammation are restricted to the superficial dermis.^{207,208} A mild lymphoplasmacytic infiltrate surrounds eccrine ducts in the superficial dermis.⁶⁵ There are no features of lichen sclerosus et atrophicus. Dermal elastic fibers are not appreciably diminished, but there is some loss of CD34⁺ spindle cells.²⁰⁷

The differentiation of morphea from the fibrotic lesions of *acrodermatitis chronica atrophicans* (see p. 681) can sometimes be difficult.²⁰⁹ Although morphea and systemic scleroderma share many histological features, the lesions of morphea are usually more inflammatory than in systemic scleroderma. Furthermore, there may be some collagen deposition in the papillary dermis in morphea;²¹⁰ it is, of course, a feature of the superficial variant. Immunofluorescence is usually negative in the lesions of localized scleroderma, although a few deposits of IgM may be found in the basement membrane zone and in small dermal blood vessels.³⁴ An increased number of cells in the dermis express factor XIIIa and vimentin, with a reduced number expressing CD34 in established lesions.^{211,212}

The cases reported as '**self-involuting atrophoderma**' occurred as non-indurated, slightly depressed lesions on the lateral upper arm that disappeared spontaneously within a year.²¹³ There was some fibrosis of the lower dermis, but not the subcutis. This is best regarded as a variant of morphea.

Dermoscopy of morphea features fibrotic beams and linear branching vessels, whereas lichen sclerosus is more prone to show whitish patches and comedo-like openings.²¹⁴ Another dermoscopic study pointed out 'chrysalis' or crystalline structures (white orthogonal or linear streaks seen with polarization dermoscopy) and elongated, looped telangiectasias in extragenital lichen sclerosus and ring-like, lilac vessels in morphea.²¹⁵

Electron microscopy

There is disarray and variable thickness of collagen at the advancing border.²¹⁶ Endothelial cells in blood vessels contain vacuoles, and there is widening of the gap between the cells.¹⁹⁶ Collagen fibrils in the subcutis have a reduced diameter.²¹⁷

Differential diagnosis

Virtually any condition associated with thickening of dermal collagen could create confusion with morphea. The appearance of 'smudged' dermal collagen can be seen as 'normal' background change in tissue sections from certain laboratories, probably as a result of fixation or tissue handling issues. In this situation, it is often clear from the history that a sclerosing condition is not a clinical concern. Dermis often appears thickened in biopsies obtained from the trunk, especially the back and abdomen, or from skin overlying large joints such as the shoulders and hips. Knowledge of the biopsy site is therefore important, and a search for characteristic inflammatory features or sweat gland 'entrapment' is helpful. Morphea can be difficult to distinguish from hypertrophic scar or keloid, especially the keloidal form of morphea. Surgical scars tend to be well demarcated, with normal-appearing connective tissue outside the immediate scarred site. A lymphoplasmacellular infiltrate concentrated at the dermal-subcutaneous junction, homogeneous appearance of the affected collagen, and atrophic sweat glands encased in dense collagen would be features expected in morphea rather than scar. Mizutani *et al.* observed that tenascin expression in involved skin of morphea is at an intermediate level and tends to be long lasting, whereas scarred lesions show marked but short-lived tenascin expression.²¹⁸ Late-stage radiation dermatitis can show swollen, hyalinized collagen bundles and loss of follicles, producing a resemblance to morphea. Changes that suggest radiation injury include hyperkeratosis, variable acanthosis, occasionally atypical keratinocyte nuclei, thick-walled vessels with luminal

occlusion, and bizarre radiation fibroblasts. Ischemic changes due to vessel occlusion, calciphylaxis, prolonged pressure, and/or ingestion of drugs such as barbiturates can result in a degenerated, amorphous appearance of dermal collagen, potentially raising the possibility of morphea. In such cases, evidence of vessel occlusion and/or calcification, or necrosis of epidermis or eccrine sweat glands, should provide a clue to the diagnosis of ischemic injury. Lichen sclerosus can be mimicked by morphea; this is particularly the case when there is papillary dermal edema or in examples of superficial morphea. However, only lichen sclerosus is likely to show hyperkeratosis, follicular plugging or epidermal atrophy with vacuolar alteration of the basilar layer; often, there is a mid-dermal, band-like infiltrate. Elastic tissue stains such as Verhoeff–van Gieson can also show preserved elastic fibers in the papillary dermis, whereas they are diminished to absent in lichen sclerosus. With regard to nephrogenic systemic fibrosis, a history of chronic renal failure and hemodialysis is obtained in most cases. Although this disorder shows significant dermal thickening, there are numerous spindled cells within the dermis and superficial subcutis and there is often accompanying interstitial mucin, producing a resemblance closer to scleromyxedema than to morphea. In addition, prominent CD34⁺ cells are observed in lesions of nephrogenic systemic fibrosis, whereas an absence of CD34⁺ cells is usually noted in the involved foci in morphea. In the study from Mexico City referred to previously, fibrosis was present in all cases with SCS but only in two of nine cases with progressive facial hemiatrophy (Parry–Romberg syndrome).¹⁷⁵ Adnexal atrophy and mononuclear cell infiltrates were also more common in SCS cases.¹⁷⁵ The distinctive atrophic follicular changes in SCS have also been described in permanent alopecia due to chemotherapy and following bone marrow transplantation,²⁰² but other morphea-like changes are not identified in that condition. The presence of histiocytes (macrophages) surrounding individual collagen fibers in the dermis has been called the 'floating sign'. However, this change is better recognized as a feature of interstitial granulomatous dermatitis – a condition with histopathologic features quite different from those of morphea. The floating sign has also been reported in intermediate-stage *Borrelia* infection, which may have overlapping features of morphea, and the interstitial variant of mycosis fungoides, in which case the collagen bundles are surrounded by neoplastic T lymphocytes.²¹⁹ Early morphea can show perineural as well as perivascular lymphocytic inflammation – findings that can mimic paucibacillary leprosy as encountered in indeterminate leprosy; this can be a significant differential diagnostic issue in regions in which leprosy is endemic.²²⁰ In such instances, biopsy of more indurated lesions will show the characteristic changes of morphea.

SYSTEMIC SCLERODERMA

Systemic scleroderma (systemic sclerosis) is an uncommon connective tissue disease characterized by symmetrical tightness, thickening and induration of the skin, Raynaud's phenomenon, and sometimes involvement of one or more internal organs.^{221–223} The spectrum of systemic scleroderma ranges from a relatively mild form with limited acral skin involvement to a more rapidly progressive diffuse form with early and significant involvement of various internal organs.^{18,221}

Diffuse systemic scleroderma

The diffuse form accounts for 20–40% of cases of systemic scleroderma. There is usually truncal and acral skin involvement of abrupt onset, associated with the appearance of Raynaud's phenomenon and constitutional symptoms.²²¹ Synovitis is common. Other features include esophageal hypomotility and strictures, rectal prolapse, sigmoid volvulus, nodular regenerative hyperplasia of the liver, primary biliary cirrhosis, idiopathic pulmonary fibrosis, pulmonary hypertension,

Sjögren's disease, thrombosis of major vessels,^{224,225} intrauterine fetal death,²²⁶ and renal failure.²²¹ Neurotropic ulceration secondary to peripheral neuropathy is a rare occurrence.²²⁷ Left ventricular noncompaction, myopathy, and polyneuropathy were associated with cutaneous sclerosis in one case.²²⁸ Scleroderma-like cutaneous sclerosis developed in a patient treated with docetaxel for prostate carcinoma.²²⁹

Limited systemic scleroderma

The limited variant of systemic scleroderma typically affects older women. Raynaud's phenomenon often precedes the onset of cutaneous thickening, which is usually limited to the digits.²³⁰ Hair loss and anhidrosis are present in affected areas. Facial telangiectasia and cutaneous calcification often develop, and there is an increased incidence of late-onset pulmonary hypertension. Anticentromere antibodies are present in up to 70–80% of patients.^{231–236}

Limited systemic scleroderma includes the condition referred to as the CREST syndrome,^{237,238} which derives its name from the clinical features of calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia.²³⁹ Not all of these features are invariably present, leading to suggestions that this term should be dropped in favor of the term 'limited systemic scleroderma'.²⁰ Another variant combines Raynaud's phenomenon, anticentromere antibodies, and digital necrosis without sclerodactyly.²⁴⁰ Glomerulonephritis is a rare association.²⁴¹ A patient with localized systemic scleroderma developed abrupt thickening and induration of the skin following an episode of borreliosis. This component of her illness resolved after specific antibiotic therapy for the *Borrelia* infection.²⁴² Limited systemic sclerosis has been reported in association with discoid lupus erythematosus in two Japanese patients with anticentromere antibodies.²⁴³

Pigmentary changes may be found in both the diffuse and the limited forms of systemic scleroderma.²⁴⁴ They may take the form of vitiligo-like areas with perifollicular and sometimes supravascular sparing, diffuse hyperpigmentation with accentuation in sun-exposed areas, or pigmentary changes in areas of sclerosis.^{245,246} Reticulate hyperpigmentation is another variant.²⁴⁷ Livedo reticularis and livedoid vasculitis with ulcers occur uncommonly.²²⁵ Macrovascular involvement as detected by arteriography is not rare in patients with digital ulceration or gangrene.²⁴⁸

Other clinical features of systemic scleroderma include a weak association with certain HLA antigen types, particularly DR5 and DR1,²⁴⁹ and rare familial cases.^{250–252} Antinuclear antibodies are present in almost all patients, usually with a speckled or nucleolar pattern.^{233,253–255} Further characterization of these antibodies is possible now that specific nuclear macromolecules have been identified.²³³ Autoantibodies to the Fc receptor are present in approximately 50% of cases,²⁵⁶ whereas antibodies to Scl-70 (antitopoisomerase) are present in approximately 30% of patients.^{221,257,258} Patients with these ANA antibodies are more susceptible to vascular disease and pulmonary fibrosis.²⁵⁹ A patient with systemic lupus erythematosus and topoisomerase I antibody has been reported.²⁶⁰ A subset of patients with lupus-like features has anticardiolipin antibodies.²⁶¹ These antibodies may have a role in the genesis of vascular involvement related to systemic scleroderma.²⁶² Antibodies to the cytoplasmic antigen Ro/SSA are present in approximately one-third of cases.²⁶³ Antineutrophil cytoplasmic antibodies of perinuclear type (p-ANCA) are present in a small number of patients.²⁶⁴ Systemic angiitis has been reported as a rare complication of systemic sclerosis, but the p-ANCA status has been reported in only one of these cases.^{264,265} The serum levels of various enzymes and substrates involved in the sclerotic process have been used as an indicator of disease activity. They include xylosyltransferase (involved in proteoglycan metabolism),^{266,267} tissue inhibitors of metalloproteinase-2,²⁶⁸ matrix metalloproteinase-9,²⁶⁹ soluble vascular adhesion molecule 1 and E-selectin,²⁷⁰ type I collagen degradation products,²⁷¹ and hyaluronan.²⁷² Thirty cases of lymphoma have been

reported to arise in association with systemic sclerosis – recently an example of small lymphocytic lymphoma in a patient with CREST syndrome.²⁷³

Pathogenesis of scleroderma

Although the pathogenetic basis for the fibrosis in scleroderma is still not elucidated, theories relate this to changes in the vascular system, immune disturbances, or alterations of fibroblast function.^{221,274–277} It is probable that these three factors will prove to be interdependent and interrelated.²⁷⁶ Infection with parvovirus B19 has also been suggested as an etiological agent.^{278–280} Abnormal immune reactions to this virus might be a consequence of the infection. The virus is known to infect endothelial cells and stromal fibroblasts; it was found by PCR in these cells in all of the cases reported by Magro and colleagues.²⁷⁹

Vascular changes include the formation of gaps between endothelial cells, alterations in the composition of type IV collagen in vascular basement membrane,²⁸¹ reduplication of the basal lamina, and disruption of endothelial cells.²⁷⁵ It has been suggested that the endothelial cell is the principal target;²⁸² endothelial dysfunction precedes other cutaneous changes in systemic scleroderma.^{283,284} These changes are associated with increased serum levels of endothelial adhesion molecules and endothelium-associated cytokines.²⁸⁵ An increase in the number of pericytes has also been observed in the marginal zones of active disease.²⁸⁶ Cutaneous hypoxia, which results from the fibromucinous intimal change in larger vessels, may play a role in the modulation of dermal fibroblast activity.²⁸⁷

Alterations in the *immune system* include the presence of autoantibodies and circulating immune complexes^{231,288} as well as an increase in the T-helper/T-suppressor cell (CD4/CD8) ratio.^{275,289} A clonal population of T cells has been found in lesional skin in patients with limited scleroderma; it is much less frequent in the diffuse form.^{290,291} Dominant T-cell clones have also been found in the peripheral blood.²⁹² There is also an association with other autoimmune diseases and a similarity to chronic graft-versus-host disease (GVHD). It has been suggested that lymphokines and monokines produced by cells in the inflammatory infiltrate may play a role in fibroblast regulation,^{275,289,293} TGF- β appears to be one of the most important (see later). Endothelin-1, derived from keratinocytes, appears to play an important role in the pathogenesis of the skin hyperpigmentation seen in patients with systemic scleroderma.²⁹⁴ Monocytes may be responsible for the release of toxic free oxygen radicals, long thought to be involved in the pathogenesis of systemic sclerosis.²⁹⁵ Their role in the pathogenesis of bleomycin-induced sclerosis is discussed elsewhere (see p. 360). Microchimerism has also been proposed as an initiating factor in the pathogenesis of scleroderma. It refers to persistence of low levels of fetal cells in a mother after childbirth. Such cells could provide a target antigen for both cell-mediated and humoral phenomena.²⁹⁶

Numerous studies have attempted to elucidate the mechanisms controlling *fibroblast activity* in scleroderma.²⁷⁵ There is an increase in the synthesis, deposition, and degradation of collagen, proteoglycans, and fibronectin. The increased collagen may result from the accumulation of a distinct subpopulation of fibroblasts with an activated transcriptional level of collagen gene expression.^{297,298} As mentioned previously, it seems that the increased fibroblast activity in scleroderma results from the activity of cytokines, the most important of which are interleukin-4 (IL-4)²⁹⁹ and TGF- β .^{300,301} This growth factor can, in turn, induce the production of three interrelated substances – connective tissue growth factor (CTGF), platelet-derived growth factor (PDGF), and tissue inhibitor of metalloproteinase-3 (TIMP-3)³⁰² – which influence the mitogenic activity and function of fibroblasts resulting in increased collagen production.^{298,303} Whereas TGF- β is responsible for the early collagen deposition, it is maintained by the subsequent activity of CTGF.³⁰⁴ CTGF is particularly involved in the regulation of type I collagen production.³⁰⁴ Decorin overexpression

reduces TGF- β levels.¹²⁰ Collagen deposition may also be enhanced by the release of cytokines and polyamines from epidermal keratinocytes.³⁰⁵ Lysyl oxidase, which initiates cross-linkage of collagen and elastin, is increased in amount.³⁰⁶ Furthermore, the increased deposition of collagen is enhanced by reduced collagenase activity.^{307,308} This deposition is accompanied by a significantly increased amount of collagen cross-link pyridinoline.³⁰⁹ It is possible that endothelial damage followed by platelet aggregation initiates the release of PDGF and the subsequent cascade of events.³¹⁰ Some of the type III collagen that is initially produced retains the aminopeptide on its surface, resulting in the formation of thin collagen fibrils, 30–40 nm in diameter.^{311,312} These fibrils may form bundles in the subcutis or at the advancing edge or be mixed with larger diameter fibrils.³¹¹ In the later stages, the ratio of type III to type I collagen is normal.³¹³ Reactive oxygen species (ROS) produced by fibroblasts may also contribute to the pathogenesis of scleroderma.³¹⁴

Treatments include vasodilators; immunosuppressant drugs such as methotrexate, cyclosporine (cyclosporin), cyclophosphamide, and extracorporeal photopheresis; and antifibrotic agents such as D-penicillamine, colchicine, interferon- γ , and relaxin.^{147,315} Other treatment approaches include hemopoietic stem cell transplantation,³¹⁶ extracorporeal photopheresis and mycophenolate mofetil,³¹⁷ and imatinib.³¹⁸ Therapeutic approaches in *limited* systemic scleroderma include sildenafil citrate (Viagra[®]),³¹⁹ bosentan in the management of digital ulcers,^{320,321} and erythropoietin.³²² One study showed that 6 months of oral ciprofloxacin therapy improved the skin findings in patients with systemic scleroderma.³²³

Histopathology^{221,324–326}

The histopathological changes in systemic scleroderma are similar to those described previously in the localized forms, although minor differences exist (Fig. 11.3). The inflammatory changes are less marked in systemic lesions, and the deposition of collagen can be quite subtle in the early stages, particularly on the fingers. Edema fluid is present in the papillary and reticular dermis of early lesions.³²⁷ Vascular changes are sometimes more prominent, particularly severe intimal fibrosis in small arteries and arterioles (Fig. 11.4).³²⁸ Dermal telangiectasia is common in the limited form.³²⁹ These vessels may show evidence of recent or old thrombosis and adventitial fibrosis.²²⁴ Sclerosis of the papillary dermis can be seen in morphea but is absent in systemic scleroderma.²¹²

Other changes described include calcification,³³⁰ an increase in mast cells in the dermis of early lesions^{327,331} and of clinically uninvolved skin,³³² and pigmentary changes corresponding to the clinical changes. For example, the vitiligo-like areas show an absence of melanocytes and of melanin in the basal layer.^{244,245} Amyloid is a rare finding.³³³ Digital lesions with the histology of focal mucinosis have been described.³³⁴

Direct immunofluorescence is usually negative, although a few cases have been described with a speckled nuclear pattern in epidermal cells similar to that seen in mixed connective tissue disease (see later).^{335,336} Immunoperoxidase techniques show a reduced number of CD34⁺ cells.³³⁷

Electron microscopy

The changes are similar to those described for the localized form.³³⁸ Fragmented elastic fibers and irregular arrangement of microfibrils have been noted in systemic scleroderma.³³⁹

MIXED CONNECTIVE TISSUE DISEASE

Mixed connective tissue disease (MCTD) is a distinct clinical syndrome sharing some clinical features of systemic lupus erythematosus, scleroderma, and polymyositis.³⁴⁰ A major retrospective study

Figure 11.3 Systemic scleroderma with thick collagen bundles in the dermis. Inflammation is absent. (H&E)

Figure 11.4 Systemic scleroderma. There is fibromuscular thickening of the wall of a small artery with luminal narrowing. (H&E)

confirmed that MCTD is in fact a distinct clinical entity, although in a subgroup of patients, MCTD apparently evolved into another connective tissue disease with disease progression.³⁴¹ In a Norwegian study, there was a female predominance, and the incidence and prevalence of MCTD were lower than those for polymyositis, dermatomyositis, systemic sclerosis, and systemic lupus erythematosus.³⁴² It is associated with the presence of circulating antibody to ribonucleoprotein.^{343,344} Antibodies to the Sm antigen and to native DNA are usually absent.³⁴⁵ Swollen or sclerotic fingers, Raynaud's phenomenon, and arthritis are important clinical features, leading to a suggestion that the acronym SRA is more appropriate than MCTD.³⁴⁶ Less constant clinical features include muscle tenderness and proximal weakness, lymphadenopathy, alopecia, esophageal hypomotility, and pigmentary disturbances.³⁴⁶⁻³⁴⁸ Approximately 20% develop restrictive lung disease.³⁴⁶ Hypocomplementemic urticarial vasculitis has been reported in a case of MCTD.³⁴⁹

MCTD usually runs a chronic and benign course and shows a good response to systemic corticosteroids.

The terms **scleromyositis** and **sclerodermatomyositis** have been used for cases with overlap features of scleroderma and dermatomyositis.^{350,351} The sera of these patients often show a homogeneous nucleolar pattern.²⁵⁵ PM-SCL autoantibodies are present in approximately 70–90% of cases.³⁵² Other features of this disease include HLA-type associations, eczema of the hands ('mechanic's hands'), and interstitial lung disease.^{352,353} Autoimmune hepatitis and sarcoidosis were present in one case.³⁵⁴

Histopathology

If lupus-like lesions are present clinically, then a biopsy from such an area will show the features of cutaneous lupus erythematosus. Even in lesions that are not clinically typical of lupus erythematosus, the histological changes may resemble subacute lupus erythematosus.³⁵⁵ In the early stages, a biopsy from a swollen finger reveals marked dermal edema with separation of collagen bundles.³⁴⁷ In later lesions, dermal sclerosis resembling that seen in scleroderma may be present. The walls of vessels in the subcutis may be thickened with luminal narrowing. Panniculitis has been reported to show septal fibrosis and membranocystic changes of the type seen in lipodermatosclerosis.³⁵⁶ Ulcer with dystrophic subcutaneous calcification can occur.³⁵⁷

Direct immunofluorescence of uninvolved skin shows a characteristic pattern of speckled epidermal nuclear staining, with specificity for IgG.³⁵⁸

EOSINOPHILIC FASCIITIS

In eosinophilic fasciitis (Shulman's syndrome), there is a sudden onset, sometimes following strenuous physical activity, of symmetrical induration of the skin and subcutaneous tissues of the limbs.^{359,360} There is usually sparing of the fingers. Localized variants, with involvement of part of a limb, have been reported.³⁶¹ The disease usually begins in mid-adult life, but no age is exempt.^{362,363} Occurrence in siblings has been reported.³⁶⁴ Other clinical features include peripheral eosinophilia^{365,366} and hypergammaglobulinemia,³⁶⁰ although rare cases with specific immunoglobulin deficiencies have been reported.³⁶⁷ Serum levels of TIMP-1 are elevated.³⁶⁸ Visceral involvement and Raynaud's phenomenon are usually absent.³⁶⁹ Elevated rheumatoid factor and positive antinuclear antibody have been reported.³⁷⁰ An association with cutaneous T-cell lymphoma has been reported.^{371,372} The majority of affected patients experience a complete or near-complete recovery after 2–4 years, usually following steroid or PUVA bath therapy but sometimes occurring spontaneously.^{373,374}

Eosinophilic fasciitis is regarded as a variant of scleroderma.³⁷⁵⁻³⁷⁷ As in scleroderma, fibroblasts in the involved skin of patients with eosi-

nophilic fasciitis exhibit an activated phenotype.³⁷⁸ Progression to scleroderma has been documented in several circumstances,³⁷⁹ including a group of patients with the Spanish toxic oil syndrome (see p. 360). Patchy lesions of morphea are sometimes present on the trunk, which is further evidence of the close association between eosinophilic fasciitis and the various scleroderma syndromes.^{362,380,381} Eosinophilic fasciitis has also been reported as a manifestation of chronic GVHD, sometimes in association with lichen sclerosus.³⁸² It may also develop as a paraneoplastic phenomenon.³⁸³ The spirochete *B. burgdorferi* has been implicated in the etiology of some cases of eosinophilic fasciitis,^{384,385} but it has been specifically excluded in other cases.³⁸⁶ Similar changes have also resulted from exposure to trichloroethylene,³⁸⁷ radiation,³⁸⁸ the subcutaneous injection of phytonadione (phytomenadione) in the treatment of hypoprothrombinemia,³⁸⁹ and the ingestion of products containing L-tryptophan. A virtual epidemic of the eosinophilia-myalgia syndrome occurred in the United States and Japan in 1989 following alterations in the manufacturing techniques of L-tryptophan. This condition is likely to become of historical interest only.³⁹⁰⁻³⁹⁵ Atorvastatin has been implicated in one case of eosinophilic fasciitis.³⁹⁶ Other possible associations include intravenous iron infusions³⁹⁷ and *Mycoplasma arginini* infection.³⁹⁸ Eosinophilic fasciitis has been accompanied or followed by aplastic anemia³⁹⁹ and paroxysmal nocturnal hemoglobinuria.⁴⁰⁰

Although spontaneous recovery is possible, most patients respond to corticosteroids.⁴⁰¹ Various other therapies have been used because no single treatment works in all cases.⁴⁰² Dapsone is sometimes effective,⁴⁰² and there are reports of a favorable response to D-penicillamine.⁴⁰³ Infliximab has been used successfully in corticosteroid-resistant cases.⁴⁰⁴

Histopathology^{362,405}

The earliest changes occur in the interlobular fibrous septa of the subcutis and the deep fascia. There is edema and an infiltration of lymphocytes, histiocytes, plasma cells, and eosinophils.⁴⁰⁵ Eosinophils are sometimes quite prominent, but in most instances there are only focal collections of these cells (Fig. 11.5).⁴⁰⁶ Lymphoid nodules may also be present.

Eventually, there is striking thickening of the deep fascia and septa of the subcutis with fibrosis and hyalinization of the collagen.^{405,407} This process extends into the deep dermis, where there is atrophy of appendages associated with the sclerosis of the lower dermis. Inflammatory changes may also extend into the fibrous septa of the underlying muscle,⁴⁰⁸ but this process is not the same as eosinophilic myositis/perimyositis.⁴⁰⁹ Similar changes were seen in the L-tryptophan-related cases,⁴¹⁰ although there was greater dermal involvement in this condition; mucin and dermal sclerosis were often seen.⁴¹¹⁻⁴¹³

Immunoglobulins and C3 have been present in the walls of vessels in the fascia and subcutis in some cases.

Differential diagnosis

The major considerations in the microscopic differential diagnosis are morphea or systemic scleroderma. The sclerosis of deep dermis and subcutaneous septa seen in eosinophilic fasciitis may also be present in morphea profunda or pansclerotic morphea. Differentiation then depends on a determination of the 'center of gravity' of the sclerotic changes and subcutaneous inflammatory infiltrates. Changes concentrated in the fascia, with extension superficially, favor eosinophilic fasciitis, whereas sclerosis focused in the deep dermis and subcutis, without lesser degrees of fascial inflammation, would point toward a diagnosis of morphea. In scleroderma, there is usually a notable lack of inflammatory cells in the fascia, in contrast to the more conspicuous inflammation found in eosinophilic fasciitis.^{414,415}

Figure 11.5 Eosinophilic fasciitis. Thickening of fascial connective tissue is accompanied by an inflammatory infiltrate that includes lymphocytes, plasma cells, and, in this case, numerous eosinophils. (H&E)

ATROPHODERMA

Atrophoderma (of Pasini and Pierini) is an uncommon but distinctive form of dermal atrophy consisting of one or more sharply demarcated, depressed, and pigmented patches.^{416–419} The color varies from bluish to slate gray or brown.⁴²⁰ There is no induration or wrinkling.⁴²⁰ Individual lesions are round or ovoid and may coalesce to give large patches of involvement. There is a predilection for the trunk, particularly the back.⁴¹⁷ In one report, the lesions had a zosteriform distribution.⁴²¹ The onset, which is insidious, usually occurs in adolescence.⁴¹⁶ It has been reported in three groups of siblings.^{422–424} Congenital idiopathic examples of atrophoderma of Pasini and Pierini have been uncommonly reported.^{425,426} Lesions may slowly progress over many years, or they may persist unchanged.

Atrophoderma is regarded by some as an abortive variant of morphea,^{427,428} an opinion favored by some overlapping clinical and histopathological features and by isolated reports of progression to either morphea or systemic sclerosis.⁴²⁹ It is probably the same condition as superficial morphea.⁶⁷ Ackerman believes it is morphea, unqualified.⁴³⁰ Others regard it as a distinct disease entity on the basis of the dermal atrophy, the usual absence of sclerosis,⁴¹⁶ and the unique glycosaminoglycan metabolism.⁴³¹ Unfortunately, this controversy is based on a small spectrum of clinical experience.⁴³²

The etiology and pathogenesis are unknown, but it has been suggested that macrophages and T lymphocytes that are present around the vessels in the dermis may play some role.⁴²⁷ In one report, 10 of the 26 patients studied had elevated serum antibodies to *B. burgdorferi*.⁴¹⁷ Twenty of the 25 patients treated with antibiotics showed clinical improvement.⁴¹⁷ A case report from Korea provides further support for this finding.⁴³³ Another patient has shown a dramatic response to hydroxychloroquine.⁴³⁴

Histopathology

There is dermal atrophy, but this may not be apparent unless adjacent normal skin is included in the biopsy for comparison (Fig. 11.6).^{420,435} The collagen bundles in the mid and deep dermis are sometimes edematous or slightly homogenized in appearance (Fig. 11.7).^{416,428} Elastic fibers are usually normal, although there may be some clumping and loss of fibers in the deep dermis.⁴¹⁶ Adnexal structures are usually preserved. There is a perivascular infiltrate of lymphocytes and a few macrophages; rarely, plasma cells are prominent.⁴¹⁷ The infiltrate is usually mild in the upper dermis and somewhat heavier around vessels in the deep dermis. Some superficial vessels may be mildly dilated.

The epidermis is usually normal, apart from hyperpigmentation of the basal layer. There may be a few melanophages in the superficial dermis.

Electron microscopy

In the one study known to the author, the collagen and elastic fibers were normal.⁴²⁷

Differential diagnosis

Clinical correlation is essential in the diagnosis of atrophoderma; in its absence, the microscopic interpretation can be extremely difficult, especially in early disease, in which the changes are quite mild and nonspecific. The slight degree of deep dermal sclerosis may be interpreted as a variant of normal or attributed to the usual truncal location of these lesions. A diagnosis of atrophoderma, or perhaps early morphea, may be suspected when normal adjacent skin is provided for comparison. However, the author has not seen changes or read descriptions of a septal lymphoplasmacytic panniculitis in atrophoderma – a frequent finding in early morphea. Serum antibodies to *Borrelia* are found in a minority of patients and are more likely to be found in Europe than in the United States.

SCLERODERMOID DISORDERS

The sclerodermoid disorders are a heterogeneous group of diseases in which lesions develop that may mimic clinically and/or histopathologically the changes found in scleroderma.^{17,436,437} The sclerodermoid disorders, some of which are discussed elsewhere, as indicated here, include the following:

- Sclerodermoid graft-versus-host disease
- Stiff skin syndrome
- Winchester syndrome
- GEMSS syndrome
- Pachydermoperiostosis
- Pachydermodactyly
- Acro-osteolysis
- Chemical- and drug-related disorders
- Paraneoplastic pseudoscleroderma
- Nephrogenic systemic fibrosis
- Lichen sclerosus et atrophicus
- Post-stripping cutaneous sclerosis

Figure 11.6 Atrophoderma. The images have been aligned so that the bases are photographed at the same level. **(A)** Uninvolved skin (*left*) lacks homogenization of collagen, and the subcutis is not visible. **(B)** Involved skin (*right*) displays thickened collagen and the subcutis is apparent. This indicates that despite the dermal sclerosis, lesional skin is slightly atrophic. (H&E)

- Scleredema (p. 413)
- Scleromyxedema (p. 407)
- Porphyria cutanea tarda (p. 577)
- Chronic graft-versus-host disease (see below)
- Chronic radiation dermatitis (p. 614)
- Werner's syndrome (p. 378)
- Progeria (p. 378).

No detailed mention need be made of the carcinoid syndrome⁴³⁸ and of phenylketonuria,^{439,440} both of which are exceedingly rare causes of sclerodermatous skin lesions. A spectrum of sclerodermoid disorders has been reported in phenylketonuria including morphea, atrophoderma of Pasini and Pierini, and lichen sclerosus et atrophicus.^{441,442} Melorheostosis (OMIM 155950), a rare sclerosing bone dysplasia, is sometimes associated with skin changes overlying the bone changes. They include scleroderma and focal skin thickening.⁴⁴³ In one patient, increased procollagen $\alpha_1(I)$ mRNA expression was found in dermal fibroblasts, but no obvious dermal thickening was present.⁴⁴⁴ Sclerodermoid changes have also followed the cutaneous eruption of rhabdomyolysis⁴⁴⁵ and the formation of an arteriovenous fistula for hemodialysis.⁴⁴⁶

Note that squeezing the skin with forceps, during a biopsy procedure, can produce an artifactual change locally in the dermis that resembles scleroderma somewhat on histopathological examination.

Separation of the collagen bundles at the margins of this zone or artifactual changes in the overlying epidermis may also be present.

SCLERODERMOID GRAFT-VERSUS-HOST DISEASE

Scleroderma-like lesions may develop in *chronic* GVHD that, by definition, occurs more than 100 days after transplant (see p. 60). Most patients who develop this uncommon complication of GVHD have disseminated sclerosis of the trunk and the proximal extremities.⁴⁴⁷ Atrophy of the skin is associated with a severe clinical evolution. Sometimes only localized or bullous lesions are present.^{448–450} Koebnerization has been reported in one case.⁴⁵¹ Nailfold capillary abnormalities are common in sclerodermoid GVHD and can be readily identified by dermoscopic examination.⁴⁵² Lichen sclerosus, eosinophilic fasciitis, and discoid lupus erythematosus have all been reported as manifestations of chronic GVHD.^{382,449,453,454} Most cases develop in adults; pediatric cases are rare.^{455,456}

Antinucleolar, anticentromere, and anti-Scl-70 antibodies are usually not present in patients with sclerodermatous GVHD.⁴⁴⁷

The disease is usually quite refractory to standard therapies including immunosuppression and extracorporeal photopheresis.⁴⁵⁷ Extracorporeal photopheresis seems to be less efficacious than previously thought.⁴⁵⁸ Therapy with UVA1 has proved satisfactory.⁴⁵⁷ Imatinib is

Figure 11.7 Atrophoderma. There is some thinning of the dermis (on the back). Collagen bundles are slightly thickened and homogenized. (H&E)

another potential treatment.⁴⁵⁹ Ultrasound can be used to monitor response to therapy.⁴⁶⁰

Histopathology

The sclerodermatous lesions of chronic GVHD show similar features to scleroderma, although the papillary and upper reticular dermis are involved at an earlier stage and there may be extension of the fibrosis into the subcutis (**Fig. 11.8A**).⁴⁶¹ The lichenoid changes of GVHD may also be present (**Fig. 11.8B**).⁴⁴⁷ It may occur without a preceding lichenoid stage.⁴⁵⁸ Secondary mucinosis is a rare finding.⁴⁶² In early lesions, the histological changes can be quite subtle despite the clinical features being quite overt.

STIFF SKIN SYNDROME

The stiff skin syndrome (OMIM 184900) is characterized by stony-hard skin, particularly on the buttocks and thighs, mild hypertrichosis, and limitation of joint mobility.^{463–466} It differs from restrictive dermopathy (see p. 373) but has similarities to *congenital fascial dys-trophy*.^{467,468} Both appear to be genetically determined abnormalities of dermal and fascial collagen. Abortive forms have been described.⁴⁶⁹ A

Figure 11.8 Sclerodermoid graft-versus-host disease. (A) Fibrosis involves the reticular dermis and extends into the subcutis. **(B)** The overlying epidermis shows the characteristic lichenoid changes of GVHD. Note that sclerosis also involves the papillary dermis. (H&E)

localized form of familial stiff skin syndrome has been described.⁴⁷⁰ Stiff skin syndrome has been found to be associated with mutations in the fibrillin-1 gene, resulting in increased amounts and activity of TGF- β , a profibrotic cytokine.⁴⁷¹

The Parana hard skin syndrome (OMIM 260530) was described in a Brazilian family. It differs from the stiff skin syndrome by severe growth retardation and a more malignant course.

Histopathology

In the cases reported as stiff skin syndrome, there have been mild fibrosis of the dermis and subcutis but no inflammation.⁴⁶⁴ An increase in dermal mucin was noted in some of the earlier cases, but this is not a consistent feature.⁴⁷² McCalmont and Gilliam described a lattice-like array of horizontally woven, thickened collagen bundles in the subcutis (with a normal-appearing reticular dermis) and proposed this as a characteristic feature of the disorder. Small clusters of lipocytes can be identified between these thickened collagen bands.⁴⁷³ Another case in a newborn infant described increased cellularity in the deep dermis, composed of myofibroblasts, dermal mucin deposition, and thickened fibrous septa.⁴⁷⁴ In cases reported as *fascial dystrophy*, the deep fascia is thickened four- to sixfold.⁴⁶⁷ Again, there is no inflammation.⁴⁶⁷

WINCHESTER SYNDROME

The Winchester syndrome (OMIM 277950) is an exceedingly rare inherited disorder of connective tissue that consists of dwarfism, carpal-tarsal osteolysis, rheumatoid-like small joint destruction, and corneal opacities.^{475,476} Cutaneous manifestations include a thick, leathery skin with areas of hypertrichosis and hyperpigmentation.⁴⁷⁷ A case in which the skin thickening was symmetrically banded has been reported.⁴⁷⁸

The Winchester syndrome is caused by a mutation in the gene encoding matrix metalloproteinase-2 (MMP-2) that maps to chromosome 16q13.⁴⁷⁹ Winchester and NAO (nodulosis-arthropathy-osteolysis) syndromes are allelic. MMP-2 is also known as type IV collagenase because it specifically cleaves type IV collagen. Recently, a mutation in the membrane type-1 metalloproteinase (MMP-14) has been found; this mutation impairs pro-MMP-2 localization and is believed to be responsible for the osteolysis and arthritis associated with the syndrome.⁴⁸⁰

One study reported an abnormal oligosaccharide in the urine of two unrelated patients with this condition.⁴⁸¹ It is possible that this and another case^{481,482} are examples of infantile systemic hyalinosis (see p. 444) and not the Winchester syndrome.

Histopathology

There is increased pigmentation of the basal layer and some thickening of the dermis. Fibroblasts are markedly increased in number, although in late lesions there are only a few fibroblasts in the thickened masses of amorphous collagen.⁴⁷⁶ A perivascular lymphocytic infiltrate is also present. There is no increase in mucopolysaccharides in the dermis.

Electron microscopy

Dilated and vacuolated mitochondria are seen in dermal fibroblasts.⁴⁷⁶ Cytoplasmic myofilaments, a prominent fibrous nuclear lamina, and some dilatation of the rough endoplasmic reticulum have also been noted.⁴⁷⁷

GEMSS SYNDROME

GEMSS syndrome (OMIM 137765) – a rare, autosomal dominant disorder – features glaucoma, lens ectopia, microspherophakia, stiff-

ness of the joints, and shortness. Sclerosis of the skin is sometimes present. This appears to be due to enhanced gene expression of TGF- β .⁴⁸³ The gene defect has not been characterized.

Histopathology

The changes resemble those seen in systemic scleroderma.

PACHYDERMOPERIOSTOSIS

The clinical manifestations of this rare syndrome (OMIM 167100) include digital clubbing; thickening of the legs and forearms resulting primarily from periosteal new bone formation at the distal ends of the long bones; and progressive coarsening of facial features with deeply furrowed, thickened skin on the cheeks, forehead, and scalp (cutis verticis gyrata).^{484,485} A case associated with folliculitis decalvans and tufted hair folliculitis has been reported.⁴⁸⁶ Pachydermoperiostosis has an insidious onset, usually in adolescence, and a self-limited course. There is a predilection for males.⁴⁸⁷ A familial incidence is sometimes present, and in these cases the inheritance is thought to be autosomal dominant with incomplete penetrance and variable expressivity of the gene.^{488,489} No candidate gene has been identified.

Associated clinical conditions have included myelofibrosis,⁴⁹⁰ protein-losing enteropathy,⁴⁹¹ and psoriatic onychopathy.⁴⁹²

This condition has also been referred to as primary hypertrophic osteoarthropathy to distinguish it from a secondary form that is usually associated with an intrathoracic neoplasm.^{493–496} Facial and scalp changes, usually less severe than in pachydermoperiostosis, have been reported in some individuals with the secondary form.^{484,497–499} Finger clubbing may be the sole manifestation in some relatives of patients with pachydermoperiostosis, indicating the overlap between these conditions.^{484,493,500}

The pathogenesis is unknown, although many mechanisms have been postulated for the secondary form. Increased peripheral blood flow is found in secondary hypertrophic osteoarthropathy but not in the primary variant.⁵⁰¹ One study showed an increased tissue sensitivity to circulating sex hormones, and this could induce enhanced tissue epidermal growth factor/TGF- α production and utilization.⁵⁰² Another study found that fibroblasts from affected skin synthesize decreased amounts of collagen but increased amounts of the small dermatan sulfate-containing proteoglycan decorin.⁵⁰³ Studies suggest that mutations in the prostaglandin transporter gene *SLCO2A1* are a cause of pachydermoperiostosis with myelofibrosis, reflecting the significant role of local prostaglandin excess in this syndrome.⁵⁰⁴ Mutations in the same gene may also be a major cause of the disorder in Japanese patients.⁵⁰⁵

Histopathology^{487,506}

The epidermis may be normal or mildly acanthotic. There is a diffuse thickening of the dermis with closely packed, broad collagen bundles. Some hyalinization of the collagen is usually present. Fibroblasts are increased in number in some areas. The subcutis may also participate in the fibrosing reaction. Elastic fibers are usually normal, although variations have been recorded. Acid mucopolysaccharides are sometimes increased in the dermis.^{489,507} In late stages, there is some thickening of capillary walls with an increase in pericapillary collagen.⁵⁰¹

Other changes include a variable, usually mild, perivascular⁵⁰⁸ and periappendageal chronic inflammatory cell infiltrate and prominence of sebaceous and eccrine glands.⁵⁰⁹

PACHYDERMODACTYLY

Pachydermodactyly is characterized by fibrous thickening of the lateral aspects of the proximal interphalangeal joints of the fingers.^{510–515} In

contrast, knuckle pads, which have similar histological appearances, involve the dorsal aspect of the finger joints.

Pachydermodactyly and knuckle pads are usually regarded as localized forms of superficial fibromatosis. Accordingly, they are considered with the fibromatoses in Chapter 34, page 976.

ACRO-OSTEOLYSIS

Acro-osteolysis refers to lytic changes in the distal phalanges. There is a familial form, an idiopathic form with onset in early adult life, and an occupational variant related to exposure to vinyl chloride.⁵¹⁶ Acro-osteolysis has also been associated with lupus erythematosus,⁵¹⁷ psoriasis,⁵¹⁸ and diabetes mellitus.⁵¹⁹ Cutaneous lesions have been described in only some idiopathic cases;⁵¹⁶ in contrast, they are a characteristic feature of occupational acro-osteolysis.⁵²⁰ There are sclerodermoid plaques on the hands accompanied by Raynaud's phenomenon.⁴³⁶ With altered work practices, occupational acro-osteolysis should become a historical disease.⁵²¹

Histopathology⁵¹⁶

The dermis is thickened, with swollen collagen bundles and decreased cellularity. There is usually no significant inflammation, and there is no calcinosis. Elastic fibers are often fragmented.

CHEMICAL- AND DRUG-RELATED DISORDERS

Sclerodermoid lesions may develop in the skin following occupational exposure to polyvinyl chloride (acro-osteolysis; discussed above), vinyl chloride monomer,⁵²² trichlorethylene,⁵²³ perchlorethylene, aromatic hydrocarbon solvents, herbicides,⁵²⁴ certain epoxy resins, and silica.^{521,525–529} Silica has also been implicated in the etiology of scleroderma.^{525,530} In recent years, there has been considerable controversy about the relationship between scleroderma and other connective tissue diseases and the use of breast prostheses containing silicone gel.^{528,531–534} Notwithstanding this debate about the possible systemic effects of extravasated silicone, it is acknowledged that a localized, dense collagenous reaction may ensue following such an event (see p. 453).

The injection of phytonadione (phytomenadione, vitamin K₁),^{535–539} polyvinylpyrrolidone (a former plasma expander),⁵⁴⁰ or pentazocine^{17,541} will result in a localized sclerodermatous reaction (Fig. 11.9). The injection of narcotic drugs may result in the 'puffy hand syndrome', a form of lymphedema that mimics edematous scleroderma.⁵⁴²

The ingestion of an olive oil substitute – rapeseed oil, denatured with aniline – produced a multisystem disease of epidemic proportions in Spain some years ago.⁵⁴³ Sclerodermoid lesions developed in the skin.⁵⁴⁴ A similar multisystem illness followed the ingestion of products containing L-tryptophan following alterations in the manufacture of this product in 1989.³⁹⁰ In both conditions, the tissue fibrosis may result from the stimulation of fibroblasts by cytokines such as TGF- β and platelet-derived growth factor.³⁹⁰

The chemotherapeutic agent bleomycin will produce cutaneous sclerosis, particularly involving the fingers, in addition to its other complications of alopecia, cutaneous pigmentation, and pulmonary toxicity.^{545–547} A sclerodermoid reaction has also been produced by peplomycin, an analogue of bleomycin.⁵⁴⁸ The cutaneous lesions produced by bleomycin in particular, and to a lesser extent by some of the other agents listed previously, are self-limiting, with some resolution of the lesions after withdrawal of the offending agent. Experimentally, mice with bleomycin-induced dermal sclerosis had a reduction in this sclerosis following injection of superoxide dismutase, supporting a role for superoxide radicals in the pathogenesis of the fibrosis.⁵⁴⁹

Figure 11.9 Sclerodermoid changes due to injection of pentazocine. The dermal sclerosis in this case has a 'wood grain' appearance. (H&E)

A sclerodermoid reaction has been produced by recombinant IL-2 (aldesleukin) used in the treatment of renal carcinoma.⁵⁵⁰ The second-generation anticancer drug uracil-tegafur (UFT) has been associated with a sclerodermatous reaction.⁵⁵¹ A similar reaction is also produced by docetaxel and paclitaxel, two of the newer antineoplastic drugs belonging to the group of taxanes.^{552–556} Gemcitabine, a new nucleoside analogue used in the treatment of certain solid cancers,⁵⁵⁷ and methysergide, used in migraine prophylaxis, have both produced sclerodermoid changes of the lower extremities.⁵⁵⁸ Sclerodactyly-like changes have been produced by capecitabine, a drug that is metabolized into 5-fluorouracil.⁵⁵⁹ The sclerodermoid reaction produced by doxorubicin and cyclophosphamide in a patient with breast cancer involved 80% of total body area.⁵⁶⁰

Histopathology

The changes resemble quite closely those found in systemic scleroderma. In bleomycin-induced lesions, the homogenized collagen is often most prominent around blood vessels and adnexal structures.

PARANEOPLASTIC PSEUDOSCLERODERMA

Sclerotic skin lesions resembling systemic scleroderma are a rare complication of malignancies. This paraneoplastic syndrome is most often seen with lung cancer, plasmacytoma, and carcinoids.^{561,562} Marked expression of $\alpha_1(I)$ collagen and CTGF mRNA, but not TGF- β_1 , was found in fibroblasts.⁵⁶¹

Histopathology

The changes in the dermis resemble those seen in systemic scleroderma or eosinophilic fasciitis.⁵⁶³ The fibrosis sometimes extends into the subcutis.⁵⁶² In a study of cases associated with plasma cell dyscrasia, light-chain restricted plasma cells were found on biopsy, and in three of five cases the plasma cells stained for TGF- β .⁵⁶³

NEPHROGENIC SYSTEMIC FIBROSIS

Although considered in this chapter in a previous edition, nephrogenic systemic fibrosis (nephrogenic fibrosing dermopathy) is histologically similar to scleromyxedema, but it does have changes in the

subcutaneous fat not seen in scleromyxedema. Accordingly, it is considered in Chapter 13, page 410.

LICHEN SCLEROSUS ET ATROPHICUS

Lichen sclerosus et atrophicus (LSA) is a chronic disorder with a predilection for the anogenital region of middle-aged and elderly women.^{564–568} Patients present with itching, pain, and/or dyspareunia.⁵⁶⁹ Cases in childhood are uncommon.^{570–573} They may be mistaken for child sexual abuse.⁵⁷⁴ Approximately 20% of patients have extragenital lesions, which sometimes occur without coexisting genital involvement.⁵⁷⁵ Extragenital sites that are affected include the upper part of the trunk, the neck, the upper part of the arms, the flexor surfaces of the wrists, and the forehead. Very rarely, palmar,⁵⁷⁶ plantar,^{577,578} and digital⁵⁷⁹ skin, the face,^{580–582} scalp,^{583,584} lips,^{585,586} mouth,⁵⁸⁷ gingiva,⁵⁸⁸ and even a surgical⁵⁸⁹ or burn scar,^{590,591} chronic wound,⁵⁹² stoma,^{593,594} and a vaccination site⁵⁹⁵ have been involved. Nail dystrophy is rare.⁵⁹⁶ Extragenital lesions may rarely follow Blaschko's lines.^{597,598} Bilateral zosteriform extragenital lesions have been described.⁵⁹⁹ Extragenital lesions are very rarely photoaggravated.⁶⁰⁰

LSA may involve the glans, prepuce, or external urethral meatus of uncircumcised prepubertal or adolescent males, resulting in phimosis.^{601–606} These lesions, also known in the past as balanitis xerotica obliterans, are not associated with extragenital involvement,⁶⁰¹ although isolated extragenital lesions may be seen in other males.^{607,608} LSA is the usual cause of secondary phimosis in prepubescent boys.⁶⁰⁹ LSA has developed in a case of male-to-female gender reassignment in skin formerly from the scrotum.⁶¹⁰ HPV is present in a significant number of penile lesions in children.^{611,612} A case has followed the use of alprostadil as an intracavernous injection for penile dysfunction.⁶¹³ Thyroid disease and psoriasis are commonly associated conditions.⁵⁶⁹ LSA is exceedingly rare in chronic GVHD.³⁸²

LSA commences as flat, ivory to white papules that coalesce to form plaques of varying size and shape. These develop follicular plugging and progressive atrophy leading to a parchment-like, wrinkled, flat or slightly depressed scar ('cigarette paper atrophy'). Vulval lesions may have secondary lichenification from the pruritus-related scratching, or they may coexist with hypertrophic areas – the so-called 'mixed vulval dystrophy'.⁵⁶⁵ Infrequently, hemorrhagic bullae form,^{614–620} and these may be complicated by the subsequent development of milia.⁶²¹ Small nodules and keratotic papules have been recorded as an unusual clinical manifestation.^{622,623} Linear lesions have also been described.²⁴⁷ Pigmentation due to massive melanin incontinence is another rare finding.⁶²⁴ As previously mentioned, lesions in LSA are leukodermic. This may come about by decreased melanin production, a block in transfer of melanosomes to keratinocytes, and melanocyte loss.⁶²⁵

Usually, the disorder is slowly progressive with periods of quiescence. Spontaneous involution may occur, particularly in girls⁶²⁶ at or about the menarche.^{627–631}

There is controversy concerning the relationship of LSA to morphea.^{632,633} Ackerman believes that LSA is a superficial variant of morphea. Although many authors have reported small numbers of cases of LSA coexisting with or superimposed upon morphea,^{69,634} it is suggested, but not universally accepted,⁶³⁵ that these patients have morphea with secondary lymphedema and sclerosis of the superficial dermis mimicking LSA both clinically and pathologically.⁶³³ In most but not all instances, there have been no genital lesions.⁶³⁶ However, in a retrospective analysis of 472 patients with morphea, 5.7% also presented with lichen sclerosus: 19 with extragenital lesions and 8 with genital disease.⁶³⁷ Some patients with LSA have had coexisting autoimmune diseases.^{638–641} Other rare associations include glucose intolerance or diabetes mellitus,⁶⁴² vitiligo,⁶⁴³ and sclerodermatous GVHD.⁶⁴⁴ It has developed after allogeneic stem cell transplantation.⁶⁴⁵ The role of HPV in LSA is controversial, despite its reported

role in LSA-related SCC of the penis (see later)^{455,646,647} and in penile LSA.⁶⁴⁸ HPV has also been found in penile LSA in children (discussed previously).

Extragenital lesions never undergo malignant degeneration, although in the genital region there may, uncommonly, be coexisting or subsequent SCC.^{567,649–652} In these circumstances, the tumor usually arises in the hyperplastic areas of what is a mixed vulval dystrophy.⁶²⁹ Interestingly, there is increased p53 but not Ki-67 expression in vulval lesions of LSA when compared to nonvulval lesional skin.^{653,654} The p53 changes may be of etiological significance in the development of some SCCs of the vulva arising in LSA.⁶⁵⁵ Although epigenetic inactivation of p16^{INK4a} occurs as an early event, it is insufficient for malignant transformation.⁶⁵⁶ Malignant change has been recorded in up to 5.8% of penile LSA.^{657–659} Most of these cases had concomitant HPV infection,⁶⁵⁷ although a subsequent study has refuted this association.⁶⁶⁰ Of 20 patients with SCC of the penis, 11 had a clinical history and/or histological evidence of LSA.⁶⁶¹ In a larger series of 207 cases of SCC of the penis, 68 patients were identified with LSA.⁶⁶² When LSA was associated with malignancy, it was often associated with low-grade squamous intraepithelial lesions.⁶⁶²

Although the etiology of LSA is unknown, attention has been directed at the role of *B. burgdorferi*, which has been detected by a modified silver stain and immunoperoxidase techniques in lesional skin.^{86–88} It has also been demonstrated by PCR-based techniques, focus-floating microscopy,⁶⁶³ and serology. Most of the studies have been from Austria or nearby European countries.^{664,665} Some *Borrelia*-associated cases have been reported from Japan.⁶⁶⁶ Attempts at detecting this organism in cases in the United Kingdom, United States, and Australia have been unsuccessful.^{100,666,667} It is possible that this geographical association is related to the presence of the genotypes *B. garinii* and *B. afzelii* in Europe but not in the United States, where *B. burgdorferi sensu stricto* is the usual species of *Borrelia* found. This particular strain does not appear to be associated with LSA. *Borrelia burgdorferi* can also be detected in cases of morphea, Lyme disease, and atrophoderma of Pasini and Pierini; this latter condition has been reported in patients with LSA.⁶⁶⁸ A patient with hepatitis C infection who developed lichen sclerosus–lichen planus overlap has been reported.⁶⁶⁹

In LSA, there are numerous epidermotropic and dermal lymphocytes that are CD8⁺, CD57⁺. This profile is usually associated with viral diseases, autoimmune diseases, and malignancies.⁶⁷⁰ Morphea also exhibits CD57⁺ lymphocytes. Clonally expanded populations of T cells have been reported in the infiltrate. The low percentage of clonal T-cell receptor- γ DNA argues against a neoplastic disease but, rather, for a local immune disorder, probably against an antigen of infectious origin.^{671–673} Immunological changes appear to occur at all levels of the skin.⁶⁷⁴ Circulating basement membrane zone antibodies have been found in a small number of patients with LSA of the vulva.⁶⁷⁵ Their presence did not correlate with any clinical feature.⁶⁷⁵

The histological changes suggest that significant alteration of the extracellular matrix is occurring.^{676,677} This may, in part, be mediated by the decreased epidermal expression of CD44, which can produce increased hyaluronate accumulation in the superficial dermis.⁶⁷⁸ Increased levels of the extracellular hyaluronic acid (HA)-binding protein ITI (inter- α -trypsin inhibitor) is closely implicated in the accumulation of HA in the broad hyalinized zone of the superficial dermis.⁶⁷⁹ Circulating IgG autoantibodies to extracellular matrix protein 1 have been found in approximately 75% of patients with LSA.⁶⁸⁰ MMP-2 and MMP-9 and their tissue inhibitors are increased in vulvar lichen sclerosus. Given their roles as collagenases and gelatinases, this finding suggests that they play an important role in the collagen remodeling that occurs in this disease.⁶⁸¹

Another finding in LSA is a loss of androgen receptors in lesional skin with disease progression.⁶⁸² This may be a secondary effect rather than of etiological significance. Estrogen receptor expression is

increased in the vulva in LSA; it may be implicated in the etiopathology of the disease.⁶⁸³

Certain HLA types (particularly DQ7 but also DQ8 and DQ9) are more frequent in patients with LSA.^{641,684,685} Familial cases are rare.⁶⁸⁶

Treatments of LSA include topical ultrapotent corticosteroid ointments 0.5% for a limited time,⁶⁸⁷⁻⁶⁹⁰ acitretin (for lesions on the scalp),⁵⁸⁴ methotrexate,⁶⁹¹ tacrolimus ointment,⁶⁸⁷ low-dose ultraviolet A1 (UVA1) phototherapy,⁶⁹² psoralen-UVA (PUVA) therapy,⁶⁹³ photodynamic therapy,⁶⁹⁴ and narrowband UVB phototherapy.⁶⁹⁵ The use of tacrolimus for genital disease has been criticized because of its potential for producing squamous cell carcinoma,⁶⁹⁶ but a recent study suggests that it is safe and effective in this form of the disease.⁶⁹⁷ Therapeutic strategies using antioxidants have been suggested.⁶⁹⁸ A review and meta-analysis of controlled trials indicates that effective topical treatments are clobetasol propionate, mometasone furoate, and pimecrolimus.⁶⁹⁹

Histopathology⁷⁰⁰

Established lesions show hyperkeratosis, follicular plugging, thinning of the epidermis, and vacuolar alteration of the basal layer (Fig. 11.10). There is a broad zone of subepidermal edema with homogenization of

Figure 11.10 (A) Lichen sclerosus et atrophicus. (B) There is orthokeratotic hyperkeratosis, some basal vacuolar change and subepidermal edema and homogenization of collagen. In established lesions, the infiltrate is deeper and more dispersed. (H&E)

collagen and poor staining in hematoxylin and eosin (H&E) preparations. In later lesions, this zone becomes more sclerotic in appearance and shows more eosinophilia. Basement membrane thickening also occurs.⁷⁰¹ Expression of collagen IV and VII is increased.⁷⁰² There is dilatation of thin-walled vessels in the zone and sometimes hemorrhage. Beneath the edema there is a diffuse, perivascular infiltrate of lymphocytes, predominantly of T-cell type in the mid dermis. This infiltrate is sometimes quite sparse in established vulvar lesions, and it may contain a few plasma cells and histiocytes. Eosinophilic spongiosis was seen in a recent case – a finding that, together with excoriation and exocytosis of lymphocytes, had been previously suggested to portend a poor symptomatic response to treatment.^{655,703} Mast cells and liberated mast cell granules are also present.⁶⁶⁷ In vulvar lesions, there is also more diversity of epidermal changes, with hyperplastic areas in mixed dystrophies.⁷⁰⁴ Vulvar LSA without associated carcinoma has a mean epidermal thickness more than three times that of extragenital LSA. It resembles lichen simplex chronicus. LSA adjacent to carcinoma tends to show exaggerated epidermal thickening, basal atypia, and loss of the edematous-hyaline layer.⁷⁰⁵ The appendages are usually preserved. In a study of 35 cases of lichen sclerosus, 20% showed elastophagocytosis by macrophages, occurring at the juncture between homogenized collagen and the underlying reticular dermis; the finding was only noted in extragenital locations.⁷⁰⁶ It was speculated that this might be a contributing factor to the elastic fiber loss seen in this disease.⁷⁰⁶

A spectrum of vascular changes occurs in LSA ranging from a rare leukocytoclastic vasculitis to a not uncommon lymphocytic vasculitis and an exceedingly rare granulomatous phlebitis.^{707,708} Three forms of lymphocytic vasculitis have been recorded: (1) concentric lymphohistiocytic infiltrates with lamination of the adventitia by basement membrane material, seen typically in penile lesions; (2) lymphocytic vasculitis with dense perivascular lymphocytic cuffing with occasional fibrin deposition in vessel walls and subendothelial infiltration by lymphocytes (Fig. 11.11); and (3) intramural lymphocytic infiltrates in large muscular vessels.⁷⁰⁸

In the early stages, elastic fibers are pushed downwards by the edematous zone and subsequently destroyed.⁷⁰⁹ Fibrillin is reduced in the upper dermis, but it is normal immediately beneath the basement membrane.⁷¹⁰ Small amounts of acid mucopolysaccharide may be found in this zone. The basement membrane may focally fragment and

Figure 11.11 Lichen sclerosus et atrophicus. A lymphocytic vasculitis is present. (H&E)

Figure 11.12 Lichen sclerosus et atrophicus. Early lesion with a heavy lymphocytic infiltrate in the upper dermis. (H&E)

Figure 11.13 Lichen sclerosus et atrophicus. Interface changes with (A) basal cell death and (B) vacuolar change. (H&E)

PAS-positive material may be found in the subjacent dermis, partially as homogeneous clumps.⁷⁰⁹ Numerous invaginations and holes are present in the basement membrane zone (BMZ) at the level of the lamina lucida and lamina densa. In bullous lesions of LSA, the split occurs below the lamina densa.⁷¹¹

In early lesions, the inflammatory infiltrate is quite heavy and is superficial and band-like, mimicking lichen planus (Fig. 11.12). Basal apoptosis and vacuolar change (Fig. 11.13) accompany the infiltrate; that is, there are features of the lichenoid tissue reaction (interface dermatitis). Overlap syndromes with lichen planus have also been suggested.^{712,713} As the edematous zone broadens, the infiltrate is pushed downwards and becomes more dispersed and usually less intense. Changes also involve adnexal structures.⁷¹⁴

Melanocytic proliferations developing in LSA may show atypical features.^{715,716} Melanocytic nevi often resemble persistent melanocytic nevi. Melanocytes, nevoid or malignant, proliferating contiguously with fibrotic or sclerotic collagen, contain abundant melanin, diffusely express HMB-45, and have a higher Ki-67 labeling index than ordinary melanocytic nevi.⁷¹⁵

Microscopic features of LSA have been recorded, as an incidental finding, in acrochordons⁷¹⁷ and in the skin tag/folds of the perineum

known as infantile pyramidal (perineal) protrusion.⁷¹⁸ Another study of this protrusion showed no histological evidence of LSA.⁷¹⁹

Electron microscopy

Electron microscopy has shown degeneration and regeneration of superficial dermal collagen, the presence of collagen in intercellular spaces in the epidermis, abnormalities of the basement membrane zone, and condensation of tonofilaments in the basal epidermal cells.^{720,721}

Differential diagnosis

The edema and/or homogenization of superficial dermal collagen are the distinctive changes that allow a diagnosis of lichen sclerosus in most instances. In contrast, elastic fibers are normal or increased,⁷²² and the continuity of the BMZ is preserved, in morphea.^{723,724} Features favoring a diagnosis of LSA over lichen planus include basilar epidermotropism, basement membrane thickening, epidermal atrophy, loss of papillary dermal elastic fibers, paucity of cytoid bodies, and a lack of wedge-shaped hypergranulosis.^{712,725} Lesions of LSA may also mimic mycosis fungoides because of the presence of epidermotropism and

focally coarse collagen bundles in the papillary dermis. Monoclonal T lymphocytes have also been recorded.⁷²⁶ Incidentally, mycosis fungoides may present clinically with lesions resembling LSA.⁷²⁷ In presumptive cases with coexisting morphea, the absence of vacuolar alteration, the lack of a well-defined inflammatory infiltrate beneath the thickened dermis, and the presence of deep dermal changes of morphea are features supporting a diagnosis of morphea without coexisting LSA.⁶³³

POST-STRIPPING CUTANEOUS SCLEROSIS

The term 'post-stripping cutaneous sclerosis' is preferred to the rather cumbersome title of the original report – 'post-stripping scleroderma-form dermatitis'.⁷²⁸ The condition presents as multiple hypopigmented and indurated plaques distributed in a linear arrangement along the path of a previously stripped saphenous vein.⁷²⁸

Histopathology

There is diffuse dermal sclerosis, sometimes extending into the subcutis. There is superficial telangiectasia and/or lymphangiectasia with mild epidermal atrophy. There is often a mild deep perivascular infiltrate of lymphocytes, but this was not present in two cases seen by the author. Inflammation may not be present in older lesions.

OTHER HYPERTROPHIC COLLAGENOSSES

Collagen is increased in several conditions, but not necessarily in the manner seen in scleroderma and the sclerodermoid disorders. Connective tissue nevi and hypertrophic scars and keloids have been arbitrarily included in this section; they could also be regarded as tumor-like proliferations of fibrous tissue, other examples of which are discussed in Chapter 34.

The dermis is usually thickened and somewhat sclerotic in lipodermatosclerosis. It is considered with the panniculitides (see Chapter 17, p. 548).

CONNECTIVE TISSUE NEVI

Connective tissue nevi are cutaneous hamartomas in which one of the components of the extracellular connective tissue – collagen, elastic fibers, or glycosaminoglycans – is present in abnormal amounts.⁷²⁹ They can be subclassified on the basis of the component predominantly involved:

- Collagen type
 - Collagenoma
 - Shagreen patch
- Elastin type
 - Elastoma
- Proteoglycan type
 - Nodules in Hunter's syndrome.

Sometimes there are alterations in more than one component of connective tissue, and these lesions may simply be categorized as connective tissue nevi.^{730,731} Only the connective tissue nevi of collagen type are discussed in this section.

Collagenoma

Collagenomas (connective tissue nevi of collagen type) are rare hamartomas of the skin in which there is an increase in dermal collagen. They usually present as asymptomatic, firm, flesh-colored plaques and

nodules, 0.5–5.0 cm in diameter, on the trunk and upper part of the arms.⁷²⁹ The ear,⁷³² sole of the foot,^{733,734} and vulva⁷³⁵ are rare sites of involvement. There may be several lesions⁷³⁶ or up to 100 or more, with an onset in adolescence.^{737,738} Rapidly growing (eruptive) collagenomas have been reported in the multiple endocrine neoplasia type I syndrome⁷³⁹ and in pregnancy.⁷⁴⁰ Eruptive collagenomas have also been reported as the only lesion.^{741,742} Uncommonly, they occur in a zosteriform or linear distribution.^{743–749} A family history is sometimes present (familial cutaneous collagenoma), and in these cases there is autosomal dominant inheritance.^{737,750–753} Familial cutaneous collagenomas (OMIM 115250) result from a mutation in the *LEMD3* gene, as seen in the Buschke–Ollendorff syndrome.^{754,755}

Associated clinical features include a cardiomyopathy,⁷²⁹ Down syndrome,^{756–758} and occult spinal dysraphism.⁷⁵⁹ Uncommonly, the connective tissue nevi associated with the Buschke–Ollendorff syndrome (see p. 384) are of collagenous composition rather than of the usual elastic tissue type.^{760–763} A connective tissue nevus of collagen type has been reported in association with pseudo-Hurler polydystrophy (mucopolipidosis III)⁷⁶⁴ and in Proteus syndrome, in which the nevi are often acral, sometimes of the plantar cerebriiform type.^{765–767} Plantar collagenomas can occur in the absence of the Proteus syndrome.⁷⁶⁸

Solitary collagenomas are sometimes quite large, as seen with the cerebriiform or 'paving stone' variants on the sole of the foot.^{769,770} Sometimes a connective tissue nevus is associated with **cutis verticis gyrata**, a descriptive term for a condition of the scalp in which deep furrows and convolutions are present. The folds of skin may, however, have normal morphology.^{771,772} Other pathological associations of cutis verticis gyrata include lymphedema,⁷⁷³ mental retardation,⁷⁷⁴ adipocyte proliferation, acromegaly,⁷⁷⁵ misuse of anabolic substances,⁷⁷⁶ myxedema, Noonan syndrome,^{774,777} tumors, and the insulin resistance syndrome.⁷⁷⁸ Cutis gyrata, usually on the scalp, can be seen in the Beare–Stevenson syndrome (OMIM 123790) characterized by mutations in the transmembrane region of fibroblast growth factor receptor (*FGFR*)-2 located at chromosome 10q26. Acanthosis nigricans, skin tags, and anogenital anomalies are other features of this syndrome.⁷⁷⁹ There is a reduction in expression of tuberlin in connective tissue nevi associated with the tuberous sclerosis complex.⁷⁸⁰

Collagenomas must be distinguished from sclerotic fibromas (see p. 974), which present as tumor-like nodules. They have a characteristic histological appearance with dense collagen bundles, often in a storiform arrangement. **Athlete's nodules** are related to, but different from, collagenomas. One such example is the dermal nodule found in the sacrococcygeal region of bicycle riders.⁷⁸¹

Histopathology

The epidermis is usually normal, although an overlying epidermal nevus has been reported.⁷⁸² There is thickening of the dermis, sometimes with partial replacement of the subcutis. The collagen bundles are broad and have a haphazard arrangement (**Fig. 11.14**).⁷⁸³ Elastic fibers are more widely spaced, but this may represent a dilution phenomenon.⁷⁸³ Sometimes the elastic fibers are thin and fragmented. Some of these cases may represent papular elastorrhexis (see p. 396).⁷⁴¹ There is no increase in mucopolysaccharides. Dermal dendrocytes are reduced using antibodies against factor XIIIa.⁷⁸⁴ Calcification was present in one reported case.⁷⁸⁵

Because the collagen in collagenomas is less well packed than normal, differences in polarization colors can be seen with picrosirius red staining followed by polarization microscopy.⁷⁸⁶ The fibers appear green to yellow, in contrast to the orange to red color of normal dermal collagen.⁷⁸⁶

Shagreen patch

The shagreen patch is a distinct clinical variant of collagenoma, found exclusively in those with tuberous sclerosis. It consists of a slightly

Figure 11.14 Collagenoma. (A) The overlying epidermis is normal. Marked thickening of the dermis is apparent. (B) The broad collagen bundles have a rather haphazard arrangement. (H&E)

elevated, flesh-colored plaque of variable size, usually on the lower part of the trunk.⁷⁸⁷ It has the appearance of untanned leather. Smaller ‘goose flesh’ papules may form as satellite lesions. A case of segmental tuberous sclerosis has been reported in which there were unilateral angiofibromas and periungual fibromas as well as a shagreen patch.⁷⁸⁸

Histopathology⁷⁸⁷

There are dense sclerotic bundles of collagen, with an interwoven pattern, in the reticular dermis.⁷⁸⁹ Fibroblasts appear hypertrophied.⁷⁸⁹ There is no inflammatory infiltrate or increase in vascularity. The overlying epidermis is usually flat, although sometimes it has the pattern of acanthosis nigricans.⁷⁸⁷

WHITE FIBROUS PAPULOSIS OF THE NECK

White fibrous papulosis consists of multiple, pale, discrete, nonfollicular lesions on the lateral and posterior neck.^{790–793} The lesions are asymptomatic and gradually increase in number; eventually there may be 10–100 papules, measuring 1–3 mm in diameter. There is some clinical resemblance to pseudoxanthoma elasticum, but there are no angioid streaks. Most of the reported cases have been from Japan and Italy.⁷⁹⁴ Involvement of the trunk and upper arms has been reported.⁷⁹⁵

There is significant overlap between cases reported as white fibrous papulosis of the neck and those reported as papillary-dermal elastolysis (acquired elastolysis of the papillary dermis simulating pseudoxanthoma elasticum) – see page 400. Accordingly, it has been suggested that both entities be combined under the term ‘fibroelastolytic papulosis of the neck’.⁷⁹⁴

The etiology is unknown, but in view of the onset late in life, the condition may be the result of an age-related change in dermal collagen.^{791,796} Cultured fibroblasts express increased amounts of collagen type I mRNA.⁷⁹⁷

Histopathology

White fibrous papulosis has some resemblance to a connective tissue nevus. There is a circumscribed area of thickened collagen bundles, involving the papillary and mid dermis.⁷⁹¹ Elastic fibers are usually reduced in areas of fibrosis.⁷⁹⁴

Dermoscopic examination shows non-folliculocentric, circumscribed white areas with dotted, or short, thinned vessels.⁷⁹⁸

HYPERTROPHIC SCARS AND KELOIDS

Hypertrophic scars and keloids are a variation of the optimal wound healing process.^{799–802} Keloids have been defined as cutaneous scars that extend beyond the confines of the original wound, and hypertrophic scars have been defined as raised scars that remain within the boundaries of the wound.⁸⁰³ Because the clinical distinction may be blurred, the usefulness of these definitions has been questioned.⁸⁰⁴ Equally, the histopathological definitions proposed here have been criticized on the grounds that they do not always correlate with the preceding clinical definitions.⁷⁹⁹ The differences between keloids, hyperplastic scars, and the optimal (normal) wound healing process are of degree only, and it is not surprising that cases with overlap features exist. A review summarizes the roles of various growth factors, cytokines, extracellular matrix proteins, and proteolytic enzymes involved in the formation of hypertrophic scars.⁸⁰⁵ Keloids may be quite disfiguring and have therefore attracted much more attention than hypertrophic scars.

Keloids are firm, variably pruritic masses, usually at the site of injury.⁸⁰⁶ They may be unevenly contoured. Early lesions are erythematous, whereas older lesions are usually pale, although occasionally they may be pigmented.⁸⁰⁴ Sites of predilection are the upper part of the back, the deltoid and presternal areas, and the ear lobes. Rare sites include the genitalia, eyelids, and even palms and soles.⁸⁰⁴ They usually develop over a period of weeks or months. Attempted surgical excision of a keloid results in regrowth of a larger lesion unless some concurrent effective therapeutic measures, such as radiation therapy or the use of cultured epithelial autografts, are adopted.^{804,807–810} Recurrence is significantly less frequent in hypertrophic scars.^{807,811}

Factors leading to the formation of keloids and hypertrophic scars include race, increased skin tension in a wound, age of the patient, wound infection, site, as already mentioned, the use of isotretinoin or cyclosporine therapy, and a predisposition to scar hypertrophy.^{799,803,812–814} Keloids may develop within adolescent striae⁸¹⁵ and secondary to therapeutic cupping.⁸¹⁶ Atrophic scars have followed acupuncture.⁸¹⁷ Hypertrophic scars have also followed patch testing, BCG vaccination, and carbon dioxide laser ablation of plantar warts in cyclosporine-treated patients.^{818–820} Keloidal plaques have been reported on the lower extremities in a patient with Ehlers–Danlos syndrome type IV.⁸²¹ Keloids are more common in black races.⁸²² They have a predilection for individuals younger than 30 years of age. A study of 14 pedigrees with familial keloids showed an autosomal dominant mode of inheritance with incomplete clinical penetrance and variable expression.⁸²³ Nine upregulated genes have been identified in keloid tissue. These

genes, especially *NNP-1* (novel nuclear protein-1), probably contribute either directly or indirectly to keloid formation.⁸²⁴

Numerous experimental studies have been designed to identify the etiology and pathogenesis of keloids. Fibroblasts isolated from keloids often synthesize normal amounts of collagen,⁸²⁵ although proline hydroxylase activity, a marker of collagen synthesis, is higher in keloids than in hypertrophic scars or normal wounds.⁸²⁶ A lower rate of apoptosis and of mutations in p53 occurs in keloid fibroblasts.^{827,828} Other studies suggest an important role for various cytokines, particularly TGF- β , which is a potent chemotactic factor for fibroblasts⁸²⁹⁻⁸³³ and stimulates them to produce major matrix components including collagen.⁸²⁹ Heat shock protein 47 (HSP47) is overexpressed in keloid fibroblasts and is another mechanism involved in collagen accumulation.⁸³⁴ IL-15 also appears to be involved.⁸³⁵ The relative amounts of type III collagen are increased. There is also increased expression of types I and III collagen mRNA.^{833,836,837} There is a major suppression of pro- α_1 (I) type I collagen gene expression in the dermis after excision of a keloid followed immediately by intrawound injection of triamcinolone acetonide – an explanation for the beneficial action of corticosteroid injections.⁸³⁸ Expression of the *gli-1* oncogene is strongly elevated in keloids compared with scars.⁸³⁹ Cultured keloid fibroblasts demonstrate the bioenergetics of cancer cells.⁸⁴⁰ Collagenase activity may be normal or increased in keloids;⁸⁴¹ decreased levels have been found in hypertrophic scars.^{842,843} Activation of MMP-9 has been demonstrated during *in vitro* mechanical compression in hypertrophic scars. It could be the effector mechanism for the regression that results from mechanical compression.⁸⁴⁴ Changes in the extracellular matrix proteins occur in keloids.⁸⁴⁵ Their interaction with TGF- β may explain their mode of action.^{846,847} Tenascin C, biglycan, integrins, and decorin are increased in some hypertrophic scars and keloids.⁸⁴⁸⁻⁸⁵¹ Expression of dermatopontin (a multifunctional protein of the extracellular matrix that influences collagen assembly) is decreased.⁸⁵² Angiotensin-converting enzyme (ACE) is significantly higher in pathological scar tissue than in normal and wounded skin.⁸⁵³ Vascular endothelial growth factor of epidermal origin appears to be increased in keloids.^{854,855} The abnormal cutaneous sensations that occur in hypertrophic scars may be the result of upregulation of opioid receptors in lesional skin.⁸⁵⁶

It appears that collagen accumulates in keloids and hypertrophic scars because there are more fibroblasts present, making more collagen than in normal wound healing, and this collagen may be protected from degradation by proteoglycan and specific protease inhibitors.^{804,857} Some degradation of collagen does occur as there is increased prolydase activity,⁸⁵⁸ but the collagen synthesis exceeds any breakdown that occurs. The *P311* gene is upregulated in hypertrophic scar tissue; this gene appears to induce a myofibroblastic phenotype and stimulates the expression of TGF- β_1 .⁸⁵⁹ A review of the genetics of keloidal scarring discusses the varying inheritance patterns, linkage loci (involving chromosomes 2q23 and 7p11), HLA alleles (including HLA-DRB1*15, HLA-DQA1*0104, DQ-B1*0501, and DQB1*0503), and a considerable number of dysregulated genes.⁸⁶⁰

Many different therapies have been used in the treatment and prevention of hypertrophic scars and keloids – an indication that no one treatment ‘cures all’. Topical treatments used include pressure therapy,⁸⁶¹ silicone gel sheeting and ointment,⁸⁶² polyurethane dressing, onion extract, imiquimod 5% cream, and vitamins A and E.⁸⁶³ Intralesional corticosteroids, laser therapy,⁸⁶⁴ cryosurgery, tissue-engineered allografts,⁸⁶⁵ intralesional 5-fluorouracil,^{866,867} or interferon- $\alpha 2b$,⁸⁶⁸ and dermojet injections of bleomycin⁸⁶⁹ have also been used. Asiaticoside, a derivative of the plant *Centella asiatica* (Indian pennywort), has been used for the treatment of hypertrophic scar for many years as an ingredient of Gotu Kola, a traditional herbal medicine.⁸⁷⁰ It appears to enhance the expression of Smad 7, which has an inhibitory effect on scar fibroblasts.⁸⁷⁰ Recombinant adenovirus-mediated double-suicide gene therapy has been used experimentally to destroy keloid

Figure 11.15 An early keloid with thick hyaline collagen replacing the scar tissue. (H&E)

fibroblasts.⁸⁷¹ Surgical management of hypertrophic scars and keloids includes the use of subcutaneous/fascial tensile reduction sutures, which minimize tension on the dermis.⁸⁷²

Histopathology^{811,873}

Early *keloids* show abundant fibrillary collagen (**Fig. 11.15**). Mature keloids have a characteristic appearance with broad, homogeneous, brightly eosinophilic collagen bundles in haphazard array (**Fig. 11.16**). Fibroblasts are increased and are found along the collagen bundles with an orientation similar to the accompanying collagen. The AgNOR count of the fibroblasts is significantly increased.⁸⁷⁴ There is also abundant mucopolysaccharide, particularly chondroitin-4-sulfate, between the bundles. Keloids have reduced vascularity compared with hypertrophic scars and normal healing wounds.⁸⁷⁵ Keloids are usually elevated above the surrounding skin surface. The overlying epidermis may be thin, and beneath it there are often some telangiectatic vessels. A sparse, chronic inflammatory cell infiltrate may surround these peripheral vessels. A study from Taiwan in 2004 reported that in scars with no detectable keloidal collagen, the features favoring the diagnosis of keloid were nonflattened epidermis, nonfibrotic papillary dermis, a

Figure 11.16 (A) Established keloid. (B) The thick hyaline bundles of collagen contrast with the more normal ones below. (H&E)

tongue-like advancing edge, a horizontal cellular fibrous band in the upper reticular dermis, and a prominent fascia-like band.⁸⁷⁶ Not all these features mirror what is described in this section. With intralesional cryo-needle procedures, the ‘swirl’ pattern of collagen bundles is lost, the thickness of the collagen layer decreases, bundles become more compact, and there is a loss of proliferating fibroblasts and mast cells in the treated site.⁸⁷⁷

In contrast, *hypertrophic scars* are only slightly elevated, if at all, above the surrounding skin. The collagen bundles are characteristically oriented parallel to the skin surface, as are the accompanying fibroblasts (**Fig. 11.17**). They are markedly increased in number, although there is some reduction in number with time. Capillaries are generally oriented perpendicular to the skin surface, and these may be surrounded by a sparse inflammatory cell infiltrate within the scar. There is little mucin except in early lesions. Elastic tissue is sparse or absent. Subepidermal clefting sometimes develops overlying a scar;⁸⁷⁸ bullae are rare.⁸⁷⁹

Mast cells are increased in both hypertrophic scars and keloids. Dystrophic calcification and bone may occasionally develop, particularly in abdominal scars.⁸⁸⁰ Alpha-smooth muscle actin has also been found in both hypertrophic scars (70%) and keloids (45%).⁸⁷⁶ CD34 and factor XIIIa are not expressed in scars.^{882,883}

Figure 11.17 Hypertrophic scar. There are parallel bundles of cellular collagen contrasting with those of the dermis below the scar. (H&E)

Electron microscopy

Keloids exhibit numerous fibroblasts with prominent Golgi complexes and abundant rough endoplasmic reticulum.⁸⁸⁴ Myofibroblasts have usually not been demonstrated,⁸⁸⁴ although it has been speculated that they may be present in early lesions.⁸⁸⁵ Very fine elastic fibers can be seen in hypertrophic scars on electron microscopy, although they cannot be demonstrated by light microscopy.⁸⁸⁶

Differential diagnosis

Keloids are sufficiently distinctive that microscopic diagnosis is seldom a problem. However, the characteristic broad, homogeneous, haphazardly distributed, eosinophilic collagen bundles of keloid can occasionally be observed focally in lesions that otherwise have the overall contours of ordinary or hypertrophic scars. Other fibrotic or sclerosing conditions, including morphea and dermatofibroma, can also show keloidal areas. However, these conditions can often be excluded by clinical data or by selected microscopic features (e.g., appendageal atrophy, dermal/subcutaneous inflammation in morphea, 'curlicue' cellular arrangements, xanthomatization, or typical epidermal changes in dermatofibromas). Attention has been drawn recently to the presence of S100-positive cells, including spindle cells with mild atypia, in cutaneous scars.⁸⁸¹ Care needs to be taken in these circumstances to avoid overdiagnosis of desmoplastic melanoma. Conversely, desmoplastic melanomas can also be misdiagnosed as scars.

STRIAE DISTENSAE

Striae distensae are a common finding in adolescents of both sexes,^{887,888} particularly females, and in pregnancy (striae gravidarum).⁸⁸⁹⁻⁸⁹¹ They were found in 83% of Korean students aged 15–17 years.⁸⁹² In another study, 87% of primigravid pregnant women developed striae gravidarum.⁸⁹³ Risk factors for the development of striae gravidarum include a history of breast or thigh striae, a family history, and the race of the patient.⁸⁹⁴ Striae distensae are also found following prolonged heavy lifting.^{895,896} Striae form in association with the excess corticosteroid of Cushing's disease, with systemic steroid therapy, and with prolonged topical use of steroid preparations.^{897,898} They develop on the abdomen, lower part of the back, buttocks, thighs, and female breasts. They are significantly more common on the thighs of girls and on the knees of boys.^{892,899} They were confined to the site of a navel piercing in one pregnant patient.⁹⁰⁰ Striae may also occur in HIV-positive persons receiving protease inhibitors such as indinavir.⁹⁰¹ Ulceration of striae has been reported in a patient with systemic lupus erythematosus⁹⁰² and in another patient with glioblastoma multiforme treated with etoposide, bevacizumab, and dexamethasone.⁹⁰³ Leukemia cutis has been reported in striae distensae – a possible example of Wolf's isotopic response.⁹⁰⁴ In one case of annular elastolytic giant cell granuloma, there was sparing of the patient's striae distensae.⁹⁰⁵

Striae show a progression of clinical appearances, commencing as flat, pink lesions that broaden and lengthen and assume a violaceous color.⁸⁹⁷ The terms striae caeruleae (blue) and striae nigrae (black) have been used to describe striae distensae that appear darker than usual due to increased melanization.⁹⁰⁶ The color gradually fades to leave a white, depressed scar. The direction of the striae is conditioned by the mechanical forces responsible, but they are usually linear. They have been attributed to the stretching of corticosteroid-conditioned skin.⁸⁹⁵ It is possible that only minimal stress is required in some circumstances, such as adolescence.⁹⁰⁷ This continuous strain on the dermal extracellular matrix may remodel the elastic fiber network in susceptible individuals.⁹⁰⁸ The proportion of cross-linked to unlinked collagen may also be of critical pathogenetic importance.⁹⁰⁷ Estrogen receptors, and to a lesser extent androgen and glucocorticoid receptors, show increased expression in recent lesions of striae distensae. These may

be involved, in varying proportions, in the remodeling of the extracellular matrix that occurs over time in these lesions.⁹⁰⁹

Histopathology⁹¹⁰⁻⁹¹²

Striae distensae are basically scars. The epidermis is flat with loss of the normal rete ridge pattern. The dermis may be thinned, suggesting that this condition would be better considered with the atrophic collagenoses.⁹¹³ Dermal collagen bundles are arranged in parallel array, resembling a scar.⁹¹⁰ There is an increase in glycosaminoglycan content in striae.⁹⁰⁸ The Verhoeff–van Gieson stain for elastic tissue will usually show a reduction in elastic fibers (Fig. 11.18), but the orcein and Luna stains will often show many additional fine fibers.⁹¹¹ Using specific markers, it has been shown that the numbers of vertical fibrillin fibers beneath the dermal–epidermal junction and elastin fibers in the papillary dermis are significantly reduced. The elastin and fibrillin fibers in the deep dermis show realignment parallel to the skin surface.⁹⁰⁸ In older lesions, thicker elastic fibers can be seen in the affected skin.⁹¹² Early lesions (striae rubrae) are rarely biopsied. They have been

Figure 11.18 Striae distensae. (A) Focal reduction in elastic fibers is seen, especially in the right side of the figure. (B) Higher magnification of the area of apparent reduction shows a number of fine fibers. (Verhoeff–van Gieson)

reported to show vascular dilatation and a mild perivascular inflammatory cell infiltrate. Another study suggested that the early stages consist of mast cell degranulation, followed by an influx of activated macrophages that envelop fragmented elastic fibers.⁹¹⁴ The increase in elastic fibers noted in advanced lesions is presumably a later stage of repair.

Reflectance confocal microscopy shows parallel collagen bundles running perpendicular to the long axis of the lesions and parallel fine papillary dermal collagen bundles with oval-shaped dermal papillae within lesions, in contrast to rounded dermal papillae in surrounding normal skin. Thinner collagen bundles were seen in striae rubra, in contrast to those in striae alba.⁹¹⁵

FIBROBLASTIC RHEUMATISM

Only a few cases of fibroblastic rheumatism have been described since the initial report in 1980.⁹¹⁶⁻⁹²¹ There is a sudden onset of symmetrical polyarthritides and Raynaud's phenomenon and the development of cutaneous nodules, 0.2–2 cm in diameter, which are found mainly on the hands. They may be more extensive.⁹²² A patient with cutaneous nodules, but without polyarthritides, has been reported.⁹²³ The cutaneous lesions resolve spontaneously after several months.⁹²¹ The nature of the disease is unknown. The suggestion that it is a variant of non-Langerhans cell histiocytosis seems unlikely.⁹²⁴ Nevertheless, it does mimic multicentric reticulohistiocytosis clinically.⁹²⁵

Histopathology

The cutaneous nodules show a proliferation of plump spindle cells, as well as fibroblasts, set in a background of thickened collagen bundles having a whorled pattern.⁹¹⁸ The plump cells are myofibroblasts.⁹¹⁹ There is some loss of elastic tissue, but there is preservation of the vasculature. A mild, perivascular, chronic inflammatory cell infiltrate is sometimes present. The degrees of cellularity range from a density suggestive of fibromatosis to more sparsely cellular lesions. Smooth muscle actin staining, indicative of myofibroblasts, is only variably positive among spindle cells.⁹²⁶

COLLAGENOSIS NUCHAE

Collagenosis nuchae (nuchal fibroma) presents clinically with diffuse induration and swelling, usually of the back of the neck, accompanied by features suggesting low-grade inflammation.⁹²⁷⁻⁹³⁰ Extranuchal involvement has been recorded.⁹³⁰ There is a male predominance. Nondestructive recurrences occasionally develop after excision.⁹³⁰ Collagenosis nuchae has been reported in association with scleredema,⁹³¹ diabetes,⁹³⁰ lipoma and traumatic neuroma,⁹³² and Gardner's syndrome.⁹³³ In Gardner's syndrome, the lesions may occur in multiple sites and in unusual locations.⁹³⁴ The term '**Gardner-associated fibroma**' has been suggested for these lesions.⁹³⁴

Computed tomography has been used to visualize the lesions.⁹³⁵

Histopathology

Thick, disorganized collagen bundles partly replace the subcutaneous fat. The collagen merges almost imperceptibly with the lower dermis and the ligamentum nuchae. There are no inflammatory cells present, despite the clinical impression of inflammation (Fig. 11.19). Furthermore, there are very few fibroblasts, distinguishing the lesion from a fibromatosis. However, there has been a report of a desmoid fibromatosis having areas resembling collagenosis nuchae.⁹³⁶ Many of the cells express CD34; a few contain factor XIIIa.⁹³³ There is no increase in mucin, as seen in scleredema (see p. 413). Nerve entrapment is a frequent occurrence.⁹²⁸ The architectural features of nuchal fibroma are subtly different from the formless sheets of collagen without neuromatosis change seen in the Gardner-associated fibroma.⁹³⁷

Figure 11.19 Collagenosis nuchae (nuchal fibroma). Fibrous tissue replaces the subcutaneous fat. There is no inflammation. (H&E)

LIPODERMATOSCLEROSIS

Lipodermatosclerosis is characterized by circumscribed, indurated inflammatory plaques on the lower extremities. Sometimes the plaques are quite large. The erythema and woody induration are often misdiagnosed as cellulitis. The condition is mentioned here because of the dermal thickening and fibrosis. There is considerable involvement of the subcutis, and this entity is therefore considered in more detail with the panniculitides (see Chapter 17, p. 548).

WEATHERING NODULES OF THE EAR

Weathering nodules are asymptomatic, white or skin-colored nodules measuring 2–3 mm in diameter. They have a gritty texture.⁹³⁸ The lesions are usually bilateral and multiple with small chains of lesions producing a scalloped appearance of the helix. Reported cases have all been in elderly males with an outdoor occupation or hobby.⁹³⁸ The lesions appear to be more common than is currently recognized.

Histopathology⁹³⁸

The lesions are composed of a spur of fibrous tissue in which there is a focus of metaplastic cartilage that is sometimes in continuity with the cartilage of the ear. The fibrous tissue sometimes extends to the undersurface of the epidermis. It is relatively acellular, but it may contain spindle-shaped cells that are negative for S100 protein and factor XIIIa. They differ from elastotic nodules of the ear, which have severe actinic elastosis, not cartilaginous metaplasia with a spur of fibrous tissue as seen in weathering nodules.⁹³⁹

ATROPHIC COLLAGENOSSES

The microscopical assessment of dermal atrophy can be difficult in the early stages. It requires a knowledge of the regional variability in skin thickness. The age of the patient is also relevant because there is some atrophy of the skin in the elderly. Technical artifacts in the preparation of histological sections can also influence dermal thickness.

The following conditions, discussed here, can be associated with a decrease in dermal thickness:

- Aplasia cutis congenita
- Focal dermal hypoplasia
- Focal facial dermal dysplasia
- Pseudoainhum constricting bands
- Keratosis pilaris atrophicans
- Corticosteroid atrophy
- Linear atrophoderma of Moulin
- Acrodermatitis chronica atrophicans
- Restrictive dermopathy.

In addition, dermal thinning can be seen in type IV Ehlers–Danlos syndrome (see p. 376) and also in some forms of Marfan’s syndrome (see p. 403). The dermis is usually thinned in striae distensae (see p. 368), but because of the scar-like features, this condition has been considered with the hypertrophic collagenoses. The unique case with membranocystic degeneration of collagen fibers, associated with some deposition of fat, and with the clinical appearance of xanthomatosis, defies classification.⁹⁴⁰

APLASIA CUTIS CONGENITA

Aplasia cutis congenita is the term applied to a heterogeneous group of disorders in which localized or widespread areas of skin are absent at birth. Its incidence is 1–3 per 10,000 births.⁹⁴¹ The defect is most often limited to the vertex of the scalp,^{942,943} but other parts of the body such as the trunk or limbs may be affected, often symmetrically, with or without accompanying scalp lesions.^{944–948} Scalp defects range in size from 0.5 to 3 cm in diameter, but larger defects up to 10 cm in diameter have been recorded.^{949,950} Other recorded associations include limb defects,^{951–954} mental retardation,⁹⁵⁵ split cord malformations,⁹⁵⁶ oculoectodermal dysplasia, encephalocraniocutaneous lipomatosis,^{957,958} epidermal and organoid nevi,^{959–961} epidermolysis bullosa,^{941,962–966} chromosomal abnormalities,⁹⁴⁵ fetus papyraceus,^{959,967,968} and focal dermal hypoplasia.^{945,955,969} The Adams–Oliver syndrome (OMIM 100300) refers to the combination of aplasia cutis congenita and transverse limb defects.^{970,971} Other systemic abnormalities, including coarctation of the aorta, may be present.^{972,973} The gene responsible has not been identified.

The MIDAS (*microphthalmia, dermal aplasia sclerocornea*) syndrome is another distinct variant of aplasia cutis congenita presenting as linear facial skin defects. The Xp deletion syndrome, MLS (*microphthalmia with linear skin defects*) syndrome (OMIM 309801), and Gazali–Temple syndrome are similar conditions.⁹⁷⁴ It is lethal in males. There is usually a microdeletion at Xp22,⁹⁷⁵ resulting in defects in the *HCCS* (human holocytochrome C synthase) gene.^{976,977} The gene for focal dermal hypoplasia is nearby (see later). This syndrome is distinct from focal dermal hypoplasia, but it could be included with focal facial dermal dysplasia (see later).

Two publications have attempted to define distinct clinical subtypes based on the location of the skin defects and the presence of associated malformations (Table 11.1).^{945,959} Some cases have an autosomal dominant inheritance with reduced penetrance of the gene;⁹⁷⁸ others appear to be the result of gene mutation.^{945,979} The condition has been reported in one of monozygotic twins.⁹⁸⁰ Other factors that may be etiologically significant in individual cases include amniotic adhesions; intrauterine trauma; drugs, particularly the antithyroid drug methimazole (thiamazole),^{981–983} biomechanical forces from the hemispheric growth of the brain,⁹⁸⁴ and ischemia resulting from placental infarcts⁹⁸⁵ or associated with the condition fetus papyraceus.^{959,967,986} A case mimicking aplasia cutis congenita, but resulting from a congenital nevus, has been reported.⁹⁸⁷

The defect in the skin presents as an ulcer, a membranous or bullous lesion, or an area of atrophic scarring.⁹⁸⁸ Sometimes there is a ring of coarse, long hair surrounding the scalp defect (the ‘hair collar sign’).^{989–991} Dermal melanocytosis was present in one such case.⁹⁹²

Table 11.1 Frieden’s classification of aplasia cutis congenita (ACC)

Type	Clinical features
I	Scalp ACC without multiple abnormalities
II	Scalp ACC with limb reduction abnormalities
III	Scalp ACC with epidermal and organoid nevi associated with corneal opacities and psychomotor retardation
IV	ACC overlying embryological abnormalities, neural or omphalocele
V	ACC with fetus papyraceus or placental infarct
VI	ACC associated with epidermolysis bullosa
VII	ACC localized to extremities without associated abnormalities
VIII	ACC due to teratogens, virus, or drug
IX	ACC associated with malformation syndromes such as trisomy 13, ectodermal dysplasia, or Goltz syndrome

Figure 11.20 Aplasia cutis congenita, from the flank of a newborn. The epithelium overlying the defect in this case resembles periderm. (H&E)

Lesions on the scalp usually heal with cicatricial alopecia.⁹⁹³ An abnormal tendency to cutaneous scarring has been reported in two siblings with this condition.⁹⁹⁴

Skin dimpling, which may be confused with aplasia cutis congenita, has been reported as a complication of second trimester amniocentesis.⁹⁹⁵

Histopathology⁹⁵⁹

The epidermis may be absent or thin, with only two or three layers of flattened cells (Fig. 11.20). The underlying dermis is usually thin and composed of loosely arranged connective tissue in which there is some disarray of collagen fibers (Fig. 11.21).⁹⁹⁶ The dermis may resemble a scar.⁹⁹⁷ Elastic fibers may be reduced, increased, or fragmented.⁹⁹⁸ Appendages are absent or rudimentary.⁹⁹⁹ The subcutis is usually thin.

FOCAL DERMAL HYPOPLASIA

Focal dermal hypoplasia (Goltz or Goltz–Gorlin syndrome; OMIM 305600) is a rare syndrome with multiple congenital malformations of mesoderm and ectoderm, affecting particularly the skin, bones, eyes, and teeth.^{1000–1004} It is caused by mutations in the gene encoding the human homologue of *Drosophila melanogaster* Porcupine (*PORCN*), an

Figure 11.21 Aplasia cutis congenita of the scalp. Appendages are lost, and the dermis is composed of thin, widely spaced bundles of collagen. (H&E)

endoplasmic reticulum protein involved in the secretion of Wnt proteins, which are important for the development of affected organs in focal dermal hypoplasia.^{1005–1007} The gene maps to Xp11.23. It is inherited as an X-linked dominant trait, which usually is lethal in the male;¹⁰⁰⁸ however, this is not absolute because some male cases have been reported.^{1009–1011} Father-to-daughter transmission is a rare event.¹⁰¹²

Cutaneous manifestations include widespread areas of dermal thinning in a reticular, cribriform and linear pattern; soft yellowish nodules representing either herniations of subcutaneous fat through an underdeveloped dermis or heterotopic fat (a fat nevus);^{1013,1014} and linear or reticular areas of hyper- or hypopigmentation, often following Blaschko's lines.^{1000,1015–1017} Lentigo-like pigmented macules at the periphery of atrophic lesions have been reported.¹⁰¹⁸ Focal loss of hair, nail changes, total absence of skin from various sites, exophytic granulation tissue,¹⁰¹⁹ apocrine hidrocystomas,¹⁰¹⁰ lichenoid hyperkeratotic papules, giant papillomas,¹⁰²⁰ and periorificial tag-like lesions may also occur.^{1000,1015,1021} Skeletal abnormalities include syndactyly, polydactyly, and longitudinal striations of the metaphyseal region of long bones (osteopathia striata).^{1016,1022–1025} Dermal hypoplasia may be a manifestation of the Proteus syndrome.¹⁰²⁶ Rarely, only cutaneous abnormalities are present in focal dermal hypoplasia.

Figure 11.22 Focal dermal hypoplasia. Clusters of adipocytes are found in the superficial dermis, close to the epidermal base. (H&E)

Experimental studies using fibroblasts from affected skin have shown that synthesis of collagen by individual fibroblasts is normal, but that there is an abnormality in cell kinetics with reduced proliferative activity of fibroblasts.¹⁰²⁷ An absence of collagen type IV from the basement membrane zone has been reported.^{1010,1028}

Histopathology^{1000,1013,1027}

The epidermis is usually normal. There is a marked reduction in the thickness of the dermis, with some thin, loosely arranged collagen fibers in the papillary dermis. Adipose tissue continuous with the subcutaneous fat extends almost to the undersurface of the epidermis in some areas. Clusters of adipocytes may be anywhere in the dermis or in a perivascular location (Fig. 11.22).¹⁰²⁹ The extreme degree of attenuation of the collagen seen in focal dermal hypoplasia is not present in nevus lipomatosus, in which mature fat also replaces part of the dermis; furthermore, the clinical presentations of the two conditions are quite distinct.

Inflammatory cells, sometimes quite numerous, have been present in biopsies of focal dermal hypoplasia taken in the neonatal period.^{1008,1030} Other findings have included the presence of increased numbers of blood vessels and of some elastic tissue within the fat – a feature not present in normal subcutaneous fat.¹⁰³¹ Elastic fibers are markedly diminished in the dermis.¹⁰³²

Electron microscopy

One study has shown fine filamentous tropocollagen within and between collagen bundles.¹⁰³³ Another has found loosely arranged collagen bundles composed of few fibrils scattered in the extracellular matrix.¹⁰³² Rough endoplasmic reticulum and Golgi complexes are not prominent in dermal fibroblasts, which are smaller and diminished in number.^{1032,1033} Elastic fibers are scarce and of normal morphology. Multilocular fat cells, which are regarded as young fat cells, are often seen.¹⁰³³ Disruption of the basement membrane zone is also present.¹⁰²⁸

FOCAL FACIAL DERMAL DYSPLASIA

Focal facial dermal dysplasia (Brauer syndrome; OMIM 136500) and facial ectodermal dysplasia (Setleis syndrome; OMIM 227260) are

rare genodermatoses that are now thought to be the same condition.¹⁰³⁴ They are characterized by congenital, usually symmetrical, scar-like lesions of the temple.^{1035–1037} Lesions may extend onto the face. There is often a spectrum of associated facial anomalies.¹⁰³⁵ The tetralogy of Fallot was present in one case.¹⁰³⁸ Inheritance is usually as an autosomal dominant trait with incomplete penetrance,¹⁰³⁹ other patterns of inheritance have been reported in what are probably clinical variants.¹⁰⁴⁰ A 'hair collar' may surround the defect.^{1041,1042} This entity has been regarded in the past as a variant of aplasia cutis congenita⁹⁹⁸ or as an ectodermal dysplasia.¹⁰⁴³

A specific variant of facial lesion that indicates the close relationship between focal facial dermal dysplasia and aplasia cutis congenita is the preauricular skin defect characterized by oval, atrophic patches distributed in a linear pattern on the preauricular region of the face.¹⁰⁴⁴ It is thought to be the result of a persistent ectodermal groove in the region of the fusion between the maxillary and mandibular facial prominences.¹⁰⁴⁴

Histopathology

The epidermis is thin and usually depressed. There is more prominent thinning of the dermis, and this is usually associated with some decrease in elastic tissue and the absence of adnexal structures.^{1035,1043} Small bundles of striated muscle are sometimes present within the dermis.^{998,1039}

PSEUDOAINHUM CONSTRICTING BANDS

The term 'pseudoainhum' refers to congenital constriction bands that may take the form of shallow depressions in the skin or deep constrictions associated with gross deformity or even amputation of a limb or digit.^{1045,1046} The term 'ainhum' is a West African name for similar constrictive lesions, usually of the fifth toe, that lead eventually to spontaneous amputation and that probably result from the effects of repeated trauma in the genetically predisposed African patients. The amniotic band syndrome is a similar condition.¹⁰⁴⁷ Closely related are the raised linear bands that developed in the first few months of life in a few patients with localized constriction. In one case, the lesions formed at the sock line,¹⁰⁴⁸ although this may be an unrelated condition.

Acquired lesions developing later in life may occur in association with scleroderma, psoriasis, syringomyelia, leprosy, and pachyonychia congenita.^{1049,1050}

Histopathology¹⁰⁴⁵

There is marked thinning of the dermis with finger-like projections of fibrous tissue extending into the underlying subcutis. Elastic tissue may be increased in this region.

KERATOSIS PILARIS ATROPHICANS

The term 'keratosis pilaris atrophicans' refers to a group of three related disorders in which keratosis pilaris is associated with mild perifollicular inflammation and subsequent atrophy, particularly involving the face. Differences in the location and the degree of atrophy have been used to categorize these three conditions – *keratosis pilaris atrophicans faciei* (*ulerythema ophryogenes*), *keratosis follicularis spinulosa decalvans*, and *atrophoderma vermiculata* (*folliculitis ulerythematosus reticulata*). All three conditions are regarded as congenital follicular dystrophies with abnormal keratinization of the superficial part of the follicles, and they are therefore considered with other follicular abnormalities in Chapter 15, page 484. Dermal atrophy is an inconstant and disputed feature.

Histopathology

In all three variants of keratosis pilaris atrophicans, there is follicular hyperkeratosis with atrophy of the underlying follicle and sebaceous gland. There is variable perifollicular fibrosis that may extend into the surrounding reticular dermis as horizontal lamellar fibrosis. The dermis may be reduced in thickness.

CORTICOSTEROID ATROPHY

Cutaneous atrophy is an important complication of the long-term topical application of corticosteroids, especially if occlusive dressings are used or the steroids are fluorinated preparations.^{1051–1053} The injection of corticosteroids into the skin will also produce local atrophy,^{1054,1055} rarely, atrophic linear streaks develop along the lines of the overlying lymphatic vessels draining the injection site.^{1056–1059} Telangiectasia and striae are other complications that may develop.^{1060,1061}

Profound digital collagen atrophy has been reported in a patient with Cushing's syndrome.¹⁰⁶² Elevated plasma cortisol levels were present secondary to an adrenal adenoma.

The pathogenesis of corticosteroid atrophy is not completely understood. It appears to involve diminished synthesis and enhanced degradation of collagen.^{1063–1065}

Histopathology^{1060,1066}

Epidermal thinning with loss of the rete ridges is an early change. The superficial dermis often has a loose texture, and there may be telangiectasia of superficial vessels. The reticular dermis is reduced in thickness only after prolonged topical therapy. If atrophy is present, the collagen bundles may appear thin and lightly stained.¹⁰⁶⁷ At other times, the collagen appears homogenized.¹⁰⁶⁸ In some areas, fibroblasts are decreased in number. Elastic fibers are focally crowded. There may also be a reduction in the size of the dermal appendages.¹⁰⁶⁹

Electron microscopy

There is disorganization of the collagen bundles and a variable thickness of the fibers.¹⁰⁶⁷ Globular masses of microfibrils are also seen.

LINEAR ATROPHODERMA OF MOULIN

Linear atrophoderma of Moulin was first described in 1992 and is characterized by a hyperpigmented atrophoderma that follows Blaschko's lines.^{1070,1071} Telangiectatic macules were also present in one case.¹⁰⁷² Leukonychia has also been described.¹⁰⁷³ Onset is usually during childhood or adolescence. The absence of sclerosis and a lilac color are distinguishing features from linear scleroderma. The lesions are similar to atrophoderma of Pasini and Pierini, but lesions in this latter entity do not follow Blaschko's lines. It has been suggested that a postzygotic mutation in *lamin A* is a theoretical possibility as a candidate gene.^{1074,1075}

The term **congenital linear atrophoderma** has been used for an infant with depressed, hypopigmented, linear plaques of congenital onset on the lower extremity.¹⁰⁷⁶ There were some similarities to a hypopigmented and congenital form of linear atrophoderma of Moulin.

Histopathology

The appearances are similar to those described for atrophoderma. The epidermis may be normal or atrophic.¹⁰⁷³ The exact relationship of a case described with dermal inflammation and a psoriasiform epidermis is uncertain.¹⁰⁷⁷ A recent case showed basal hypermelanosis, mild thickening of reticular dermal collagen, and a sparse

perivascular lymphocytic infiltrate; ultrasound examination showed reduced thickness of subcutaneous tissue in lesional skin compared to normal skin.¹⁰⁷⁸ Another case showed clear-cut dermal atrophy with thinned collagen bundles; fragmented elastic fibers were identified in the superficial reticular dermis on Verhoeff–van Gieson staining.¹⁰⁷⁹

ACRODERMATITIS CHRONICA ATROPHICANS

Acrodermatitis chronica atrophicans is a spirochete-induced disease (see p. 681) characterized by atrophy of the dermis to approximately half its normal thickness or less. The pilosebaceous follicles and subcutis also undergo atrophy.

Acrodermatitis chronica atrophicans may coexist with juxta-articular fibrotic nodules and morphea-like lesions.^{1080–1082}

RESTRICTIVE DERMOPATHY

Restrictive dermopathy (OMIM 275210) is a recently delineated, lethal, autosomal recessive disorder characterized by taut and shiny skin with facial dysmorphism, arthrogryposis multiplex, and bone dysplasia.^{1083–1090} It has also been called the tight skin contracture syndrome. Transposition of the great arteries and microcolon are two further associations.¹⁰⁹¹

Fibroblasts show poor growth in culture, suggesting that restrictive dermopathy results from a primary abnormality in fibroblast growth and function.¹⁰⁸³

A study in 2005 showed that restrictive dermopathy is caused by mutations either in the *LMNA* gene, at locus 1q21.2 encoding A-type lamins, or in the zinc metalloproteinase STE (*ZMPSTE24*) gene, encoding a metalloprotease essentially for the post-translational processing of prelamin A to mature lamin A. The former defect is inherited as an autosomal dominant trait and the latter as autosomal recessive.¹⁰⁹²

Histopathology

There is thinning of the dermis with the collagen bundles arranged parallel to the skin surface.¹⁰⁸³ Elastic tissue may be normal or reduced in amount. Rudimentary hair follicles are usually present. There is also a reduction in adnexal structures and factor XIIIa-positive dendrocytes. The overlying epidermis is often hyperplastic with hyperkeratosis.¹⁰⁸⁸

Electron microscopy

The collagen fibrils are reduced in size with irregular interfibrillary spaces and some granulofilamentous deposits.^{1084,1085} Degenerating fibroblasts have also been noted.

PERFORATING COLLAGENOSSES

The perforating collagenoses are a group of dermatoses in which altered collagen is eliminated from the dermis through the epidermis.¹⁰⁹³ Included in this group are reactive perforating collagenosis, the closely related entity of perforating verruciform ‘collagenoma’ (collagène perforant verruciforme), and also chondrodermatitis nodularis helices.

Collagen elimination is also found as a secondary event in some cases of granuloma annulare (perforating granuloma annulare) and of necrobiosis lipoidica. It has also been seen in healing wounds, in resolving keratoacanthomas, and following the intradermal injection of corticosteroid.^{1094,1095} Some cases do not fit neatly into any of the categories listed previously.¹⁰⁹⁶

REACTIVE PERFORATING COLLAGENOSIS

Reactive perforating collagenosis, first described in 1967, is a rare condition in which collagen is eliminated from the dermis.¹⁰⁹⁷ There are two distinct clinical variants.¹⁰⁹⁸ In the usual form, in which the onset is in childhood, there are recurrent, umbilicated papules up to 6 mm or so in diameter that spontaneously disappear after 6–8 weeks, leaving a hypopigmented, sometimes scarred area.¹⁰⁹⁹ New lesions develop as older lesions are involuting, and this may continue into adult life.¹¹⁰⁰ The papules are found on the extremities, particularly the dorsum of the hands and forearms. The sole of the foot is a rare site.¹¹⁰¹ There is often a history of superficial trauma, such as a scratch or insect bite.^{1102,1103} Lesions have been induced experimentally by trauma.^{1098,1104} An association with Down syndrome has been reported.¹¹⁰⁵ An autosomal recessive inheritance has been proposed for some cases.^{1093,1106}

The other clinical variant (acquired perforating collagenosis) is acquired in adult life and occurs especially in diabetics with chronic renal failure.^{1107–1116} In patients with chronic renal failure, there is sometimes clinical and histological overlap with other perforating disorders, such as perforating folliculitis and Kyrle’s disease.^{1117–1122} The finding that both collagen and elastic fibers undergo transepithelial elimination in these circumstances suggests that a single disease process is present.¹¹²³ The term ‘acquired perforating dermatosis’ has been suggested for the different expressions of transepithelial elimination associated with renal disease and/or diabetes mellitus.^{1121,1123–1125} ‘Giant’ lesions up to 2 cm in diameter and forming plaques in some areas have been reported.¹¹¹⁵ Reactive perforating collagenosis has also been reported in association with myelodysplastic syndrome,¹¹²⁶ Hodgkin’s disease,^{1127,1128} internal cancers,^{1129,1130} herpes zoster,^{1131–1133} the Treacher Collins syndrome,¹¹³⁴ the red dye in a tattoo,¹¹³⁵ lichen amyloidosis, chemical burns from commercially available saltwater,¹¹³⁶ Wegener’s granulomatosis, hepatitis,¹¹²¹ hypothyroidism,¹¹²¹ rheumatoid arthritis, Henoch–Schönlein purpura,¹⁰⁹³ the acquired immunodeficiency syndrome associated with end-stage renal disease,¹¹³⁷ dermatomyositis,^{1138,1139} and urticarial vasculitis in pregnancy.¹¹⁴⁰ Its association with scabies and atopic dermatitis may be the result of intense scratching.^{1141–1144} Another case developed during erlotinib therapy.¹¹⁴⁵

It has been suggested that the acquired variant may be precipitated by the deposition of crystal-like microdeposits in the upper dermis, close to the site of the transepidermal channel.¹¹²⁵ Such material is possibly a by-product of the chronic renal failure.

An attempt has been made to elucidate a common mechanism for the various perforating disorders. It has been suggested that elevated serum and tissue concentrations of fibronectin (a component of the extracellular matrix) may incite epithelial proliferation and migration, culminating in perforation.^{1146,1147} TGF- β has also been implicated in this process.¹¹⁴⁸

Cases of acquired perforating collagenosis have been successfully treated with doxycycline,^{1149,1150} allopurinol,¹¹¹⁵ oral acitretin,¹¹¹⁶ and with narrowband ultraviolet B phototherapy.¹¹⁵¹ Topical retinoic acid has been used to treat familial cases.¹¹⁵²

Histopathology^{1093,1097,1102}

The appearances vary with the stage of evolution of the lesion. In early lesions, there is acanthosis of the epidermis and an accumulation of basophilic collagen in the dermal papillae. In established lesions, there is a cup-shaped depression of the epidermis that is filled with a plug consisting of parakeratotic keratin, some collagen, and inflammatory debris (Fig. 11.23). The underlying epidermis is thin with fine slits through which basophilic collagen fibers in vertical orientation are extruded. Sometimes there is a complete break in the epidermis (Fig. 11.24).¹¹⁵³ A few studies have shown elastic fibers in the extruded material and granulation tissue in the superficial dermis.¹¹⁵⁴ Follicular

Figure 11.23 Reactive perforating collagenosis. This patient had the classic form of the disease, with umbilicated papules developing in an area of superficial trauma and no history of diabetes mellitus or chronic renal failure. **(A)** There is a cup-shaped depression of the epidermis, containing keratin and inflammatory debris. The papillary dermal collagen has a slightly basophilic stain, and there is focal disruption of the epidermis (*arrow*). **(B)** Collagen fibers and inflammatory cells have entered the break in the epidermis. (H&E)

involvement was present in 40% of cases in one series.¹¹⁵² Immunohistochemical and ultrastructural studies have shown that the extruded collagen is normal.^{1125,1154} One study has shown that the extruded collagen is type IV, suggesting origin from basement membrane.¹¹⁵⁵ Nuclear material derived from neutrophils, and neutrophils themselves, is present in the extruded material.^{1156,1157} There is also absence of the basal lamina at the site of the perforation.¹¹¹⁸

PERFORATING VERRUCIFORM 'COLLAGENOMA'

Perforating verruciform 'collagenoma', also known as collagenome perforant verruciforme, is closely related to reactive perforating collagenosis. Traumatically altered collagen is eliminated in a single, self-limited episode.^{1095,1158,1159} The episode of trauma is usually more substantial than in reactive perforating collagenosis, and the lesion that results is

Figure 11.24 Acquired perforating collagenosis in a patient with chronic renal failure. **(A)** There is a cup-shaped depression containing keratin, necrotic tissue, and inflammatory debris. **(B)** Collagen fibers are being extruded into the plug. (H&E)

Figure 11.25 A variant of **perforating collagenosis** following trauma from a seat belt in an automobile. Damaged collagen is being eliminated through the epidermal downgrowths. (H&E)

more verrucous. The author has seen a large plaque develop on the chest, following trauma from an automobile seat belt, with the histological features outlined below.¹¹⁶⁰

Histopathology¹¹⁶⁰

There is prominent epithelial hyperplasia with some acanthotic downgrowths encompassing necrobiotic collagen and debris (Fig. 11.25). Elastic fibers are partly preserved in the central plug.¹¹¹⁹

CHONDRODERMATITIS NODULARIS HELICIS

Chondrodermatitis nodularis helcis is a chronic, intermittently crusted, painful or tender nodule found primarily on the upper part of the helix of the ear of males older than age 50 years. Cases younger than age 20 years are rare.^{1161,1162} The lesions are usually solitary and average 4–6 mm in diameter. There is a predilection for the right ear in some series.¹¹⁶³ The condition is infrequent in females, in whom it is more common on the antihelix.¹¹²⁷ Bilateral lesions on the free border of the helix have been reported in a woman.¹¹⁶⁴ The recurrence rate after treatment, which is usually curettage and cautery, can be as high as 20%.^{1165,1166} Lesions are now being seen as a result of chronic pressure from cell (mobile) phones.¹¹⁶⁷ The location of the lesions correlates with the point of pressure of the phone.

The etiology and pathogenesis are speculative, but it has been suggested that the primary event is localized degeneration of dermal collagen with its subsequent partial extrusion through a central ulcer or by actual transepidermal elimination. The collagen degeneration possibly results from a combination of factors that include minor trauma or pressure (during sleep),^{1168,1169} poor vascularity, and sometimes solar damage.¹¹⁶⁵ An autoantibody to type II collagen was present in one case.¹¹⁷⁰ An association with the limited form of systemic sclerosis and with dermatomyositis is a rare occurrence.^{1171,1172} Magro and colleagues have reported a series of 24 patients with an underlying systemic disease, including collagen vascular diseases, autoimmune thyroid disease, and non-immune-based vascular injury syndromes.¹¹⁷³ The patients were characteristically younger than the usual patients with this condition.¹⁰⁷³ Goette called chondrodermatitis nodularis helcis an 'actinically induced perforating necrobiotic granuloma', but this statement appears to be an overgeneralization.¹¹⁷⁴ It has also been suggested that the infundibular portion of the hair

Figure 11.26 **Chondrodermatitis nodularis helcis**. Fibrinoid material is present in the base of an ulcer that overlies the cartilage of the ear. (H&E)

follicle is primarily involved, with perforation of follicular contents into the dermis.^{1175,1176}

As previously mentioned, the usual treatment is curettage and cautery, but surgical excision is often used. Punch excision of the lesion followed by a full-thickness skin graft gives results comparable with other methods.¹¹⁷⁷ Conservative methods, aimed at removing the putative precipitating factors, namely pressure and trauma, have also been successful.¹¹⁷⁸ Topical nitroglycerin shows promise as a therapy for this condition.^{1179,1180}

Histopathology^{1181,1182}

The characteristic changes are a central area of ulceration or erosion or a more or less tight funnel-shaped defect in the epidermis overlying an area of dermal collagen that shows variable edema and fibrinoid degeneration (Fig. 11.26). Some inflammatory, keratinous and collagen debris caps the area of degenerate collagen, forming the crust noted clinically.

At the margins of the central defect, there is variable epidermal acanthosis, which rarely assumes the proportions of pseudoepitheliomatous hyperplasia.¹¹⁷⁶ It extends peripherally over three to five rete pegs, and there is usually a prominent granular layer with some overlying hyperkeratotic and parakeratotic scale.¹¹⁸² Richly vascularized granulation tissue borders the necrobiotic material peripherally, and sometimes the vessels have some glomus-like features. This area usually contains a mild, but sometimes moderately heavy, inflammatory cell infiltrate. The infiltrate is predominantly lymphocytic with an admixture of plasma cells, histiocytes, and sometimes a few neutrophils. Rarely, the histiocytes may assume a palisaded arrangement at the margins of the necrobiotic zone.¹¹⁸² Irregular slit-like spaces may extend into the degenerate collagen, and other spaces containing fibrin may be found at the dermoepidermal junction above the peripheral granulation tissue. Uncommonly, degenerate collagen will be seen in slits within the epidermis, representing true transepidermal elimination.

Beyond the lesion itself, there may be some telangiectatic vessels in the upper dermis and variable solar elastosis.¹¹⁷⁴ Elastic fibers are diminished and focally absent in the area of degenerate collagen. Nerve hyperplasia is present in most lesions, the possible mechanism of the pain that occurs with light pressure.¹¹⁸³ This change is often masked by the intense vascular and inflammatory reactions.¹¹⁸³

Figure 11.27 Chondrodermatitis nodularis helicis. This healed lesion shows fibrosis of the dermis and perichondrium. (H&E)

In nearly all cases, there are changes in the perichondrium that are most marked directly beneath the degenerate collagen. These changes include fibrous thickening and very mild chronic inflammation. Degenerative changes may also be found in the cartilage, with alterations in its staining qualities, patchy hyalinization, and, uncommonly, partial destruction with necrosis.¹¹⁸² Calcification and even ossification have been noted in the distal part of the chondral lamina.¹¹⁸⁴ In healed lesions, there is dermal fibrosis that also involves the perichondrium (Fig. 11.27).

VARIABLE COLLAGEN CHANGES

Variable changes in dermal collagen are found in Ehlers–Danlos syndrome, osteogenesis imperfecta, and Marfan’s syndrome. Marked thinning of the dermis can occur in some forms of all three disorders, although in other clinical variants it may appear quite normal. Defects in the biosynthesis of collagen have been detected in a number of patients with osteogenesis imperfecta and Ehlers–Danlos syndrome, although in the majority of cases the defect has not been defined.¹

Table 11.2 Revised (new) classification of Ehlers–Danlos syndrome	
New name	Former category (traditional classification)
Classic type	Gravis (type I) Mitis (type II)
Hypermobility type	Benign hypermobile (type III)
Vascular type	Arterial-ecchymotic (type IV)
Kyphoscoliosis type	Ocular-scoliotic (type VI)
Arthrochalasia type	Arthrochalasia congenita (types VIIA and VIIB)
Dermatosparaxis type	Human dermatosparaxis (type VIIC)
Other forms	X-linked (type V) Periodontitis (type VIII) X-linked, lysyl oxidase-deficient, occipital horn syndrome (type IX) Fibronectin-deficient (type X) Familial hypermobility (type XI) Progeroid Kyphoscoliosis type, without lysyl hydroxylase deficiency

EHLERS–DANLOS SYNDROME

Ehlers–Danlos syndrome is a heterogeneous disorder of connective tissue that combines hyperextensible fragile skin and loose-jointedness with a tendency to bruising and bleeding.^{1185–1190} Absence of the inferior labial and lingual frenula is associated with the classic and hypermobile types.¹¹⁹¹ At least 11 types are now recognized, each with a characteristic clinical expression, inheritance pattern, and, in some cases, a defined defect.^{9,1192} Paradoxically, specific defects in collagen biosynthesis have not been elucidated in the common forms of this disease.¹¹⁹³ Syndrome delineation is still proceeding, and many cases do not fit neatly into any category.¹¹⁹⁴ In 1997, a revision of the traditional classification used here was proposed, based primarily on the cause of each type.¹¹⁹⁵ This classification, which has not gained wide acceptance, is shown in Table 11.2.

Histopathology

Contradictory results have been published on the histopathology of this condition.^{1196,1197} More recent reports have generally stated that the dermis is normal on light microscopy.¹¹⁹⁶ Marked thinning of the dermis has been reported in some variants of type IV¹⁶ and also in type VI, whereas solar elastotic changes have been documented in type IV disease.¹¹⁹⁶ Elastosis perforans serpiginosa has been reported in several cases of the syndrome, again particularly type IV.¹⁰⁹³ Similarly, ultrastructural studies have been contradictory, with some authors reporting normal fiber diameter and others observing some variability in size.^{16,1198,1199} A distorted arrangement of fibrils has been noted in several reports.¹¹⁹⁸ Scanning electron microscopy may offer further information in the future because preliminary studies have shown disordered fibril aggregation and orientation.¹¹⁸⁷ Other ultrastructural findings are mentioned in the discussion of the specific types of the syndrome.

Subtypes of Ehlers–Danlos syndrome (traditional classification)

Type I (gravis)

Patients with types I (OMIM 130000) and II (OMIM 130010) Ehlers–Danlos syndrome are now referred to as having the classic type. Clinical features are usually severe in this common, autosomal

dominant (gravis) form of the disease.⁴ Herniation of fat into the dermis, with subsequent calcification, may occur at pressure points.¹²⁰⁰ Increased fiber diameter and loosely assembled fibrils have been reported.¹²⁰¹ The biochemical defect is not known, although reduced type III collagen production has been reported in one case.¹²⁰¹ Mutations have been found in the *COL5A1*, *COL5A2*, and tenascin-X genes in a limited number of patients/families.^{12,1202,1203} Failure to detect a defect in many patients with types I/II may be due to so-called 'haploinsufficiency' (loss of expression of one allele), which is present in up to one-third of individuals with this classic type.¹²⁰⁴ An arginine → cysteine substitution in type I collagen has also been reported in a family. This finding, which implicates another fibrillar collagen, confirms the genetic heterogeneity of this type.¹²⁰⁵

There is a reduction in the number of factor XIIIa-positive dendrocytes in the classic type (types I and II of the traditional classification system). There is also a reduction in skin thickness on ultrasound examination.¹²⁰⁶

Type II (mitis)

The molecular defect in this mild, autosomal dominant form is unknown.⁴ Partial deletion of the C-terminal end of the procollagen molecule has been demonstrated in one case.⁶ Minor variations in fibril diameter have been noted ultrastructurally, and in one case there was lateral fusion of fibrils.¹¹⁹⁹ It has been suggested that mild variants of the mitis form are not uncommon in the general population.^{1207,1208}

Type III (benign hypermobile)

In type III (OMIM 130020), there is marked joint hypermobility but only minor skin changes.^{4,1209} Skin thickness is reduced on ultrasound examination.¹²⁰⁶ Inheritance is autosomal dominant. Some cases are due to a deficit of tenascin-X, but no molecular alteration has been described in the majority of cases. Elastic fibers in the tenascin-X cases are fragmented and clumped.¹²¹⁰ A recessive variant of this syndrome has been related to a deficiency of tenascin-X.¹²¹¹

Type IV (arterial, ecchymotic)

Type IV is a heterogeneous group with at least four subtypes.^{1212,1213} Both autosomal dominant (OMIM 130050) and recessive variants occur.^{1212,1214} There is a reduced life expectancy because of a propensity for rupture of large arteries and internal hollow viscera, particularly the colon.^{9,1215} Thin, translucent skin on the face and distal parts of the limbs in several subtypes gives the appearance of premature aging (acrogeria; p. 379).^{1213,1216,1217} Type IV results from a mutation in the *COL3A1* gene that controls type III collagen synthesis.^{1193,1218,1219} It is located in the region of chromosome 2q31.¹²²⁰ A decreased amount of type III procollagen is recovered from cultured skin fibroblasts.^{9,1221,1222} Defective type III collagen is sometimes found.⁹ However, a case with type III collagen deficiency but with a normal phenotype has been documented.¹²²³

Vascular rupture has also been reported in patients with type I collagen R-to-C substitution, indicating the difficulty of classifying some cases with the traditional classification system.¹²²⁴

Ultrastructural changes have included the finding of collagen fibrils with reduced diameter, the presence of dilated rough endoplasmic reticulum in fibroblasts, and fragmentation of elastic fibers.¹²¹⁶ A scoring system has been developed for the diagnosis based on the ultrastructural characteristics of this vascular type – for example, abnormal fibroblasts, the presence of lysosomes in fibroblasts, or abnormal basal lamina.¹²²⁵

Immunofluorescence of cultured skin fibroblasts has shown abnormal amounts of type III collagen retained in their cytoplasm.¹²²⁶ This is not a feature in normal subjects or in other connective tissue diseases.

The presence of thin skin can be confirmed by ultrasound.¹²²⁷

Type V (X-linked)

The rare type V form (OMIM 305200) shows marked cutaneous extensibility.^{4,1186,1228} A defect in lysyl oxidase was found in one kindred, but this has not been confirmed in others.¹²²⁸

Type VI (ocular/kyphoscoliosis)

This autosomal recessive variant (OMIM 225400) is characterized by ocular fragility, kyphoscoliosis, and prominent cutaneous and joint signs.^{4,1229} There is a deficiency in peptidyl lysyl hydroxylase and an absence of hydroxylysine in dermal collagen.^{1185,1230} This results in abnormal cross-links in both type I and type III collagen.¹²³¹ The candidate gene is *PLOD1*, which maps to chromosome 1p36.3–p36.2. This variant of the syndrome is probably a biochemically heterogeneous entity because normal levels of enzyme have been found in some individuals.⁴

Type VII (arthrochalasis congenita)

There is gross joint instability leading to multiple dislocations at birth.¹²³² There are three subtypes, all of which are characterized by defects in the conversion of type I procollagen to collagen.¹¹⁹³ In types A and B, there are abnormalities in the N-terminal procollagen peptidase cleavage sites.^{1222,1233} A deletion in chromosome 6q has been reported in one patient with type VII B (OMIM 130060).¹²³⁴ A third subgroup, type VII C, results from deficient procollagen I N-proteinase.¹²³⁵ It results from inactivating mutations in the *ADAMTS-2* gene.¹²³⁶ It is similar to dermatosparaxis in cattle.^{1235,1237–1239} On electron microscopy, there are small, irregular, and circular collagen fibers in the skin.¹²³⁵

Type VIII (periodontal)

The type VIII autosomal dominant form (OMIM 130080) is marked by easy bruising, pretibial hyperpigmented scars, and the early onset of periodontal disease.^{1185,1240,1241} Periodontal disease is unique to this variant.¹²⁴² There may be loose-jointedness of the fingers. The molecular defect is currently unknown, but the gene appears to be located at 12p13.^{1242,1243} The microfibril-associated glycoprotein-2 gene (*MAGP2*) is a promising candidate gene.¹²⁴¹ A reduction in collagen type I and type III synthesis was detected in one case.¹²⁴⁴ The dermis often appears normal on light microscopy.

Type IX

The type IX variant is X-linked and characterized by the presence of occipital horns and other skeletal abnormalities and a propensity to bladder diverticula and to hernias.^{1228,1245} Cutaneous changes are mild. There is defective activity of lysyl oxidase. It has been suggested that all disorders with deficient lysyl oxidase, including Menkes' syndrome (see p. 401), should be classified as type IX disease,^{1246,1247} but this ignores the absence of the usual clinical features of Ehlers–Danlos syndrome in patients with Menkes' syndrome.

Type X (fibronectin)

Some cases of the type X variant (OMIM 225310) were originally classified as type IX disease.¹²⁴⁸ There are moderately severe skin and joint changes and a defect in platelet aggregation.¹²⁴⁸ The platelet defect can be corrected by fibronectin, which is an important adhesive glycoprotein that cross-links to collagen.¹²⁴⁸

Type XI (familial joint instability syndrome)

Joint changes are prominent in this autosomal dominant variant.^{1194,1199}

Other types

Many cases of Ehlers–Danlos syndrome defy classification, such as the case reported with abnormalities localized to the shoulder region¹²⁴⁹ and another with intracellular degradation of α_2 chains of type I procollagen.¹²⁵⁰ This same defect is found in some cases of osteogenesis

imperfecta and of Marfan's syndrome.¹²⁵⁰ Mutations in genes encoding types I and II transforming growth factor- β (*TGFBR1* and *TGFBR2*) cause the newly recognized Loeys–Dietz syndrome, which is characterized by aortic aneurysms, generalized arterial tortuosity, and a variety of craniofacial and skeletal anomalies.¹²⁴¹

It has been suggested that women with recurrent preterm premature rupture of fetal membranes may have a form of Ehlers–Danlos syndrome because examination of their skin shows a thinned dermis, with thinned collagen bundles and some ribbon-like elastic fibers.¹²⁵¹ Kosho, Miyake, and colleagues described a new type of Ehlers–Danlos syndrome that has overlapping features with the kyphoscoliosis type but without lysyl hydroxylase deficiency. Other defects in this type include craniofacial abnormalities, joint contractures, and progressive joint and skin laxity.¹²⁵² These authors have found mutations in the carbohydrate sulfotransferase 14 (*CHST14*) gene, which resulted in loss of the decorin dermatan sulfate proteoglycan, possibly interfering with proper collagen bundle formation.¹²⁵³

OSTEOGENESIS IMPERFECTA

Bone fragility is the cardinal manifestation of osteogenesis imperfecta (OI) (OMIM 166200), a genetically heterogeneous entity in which various defects in type I collagen have been detected.^{7,1254} Other clinical manifestations include short stature, joint laxity, blue sclerae, and otosclerosis. The skin may be thin in the severe variants; it has reduced elasticity.¹²⁵⁵

Histopathology

The dermis is markedly reduced in thickness in those with clinically thin skin.¹⁶ The fine collagen bundles that constitute the dermis are often argyrophilic. Using a nonlinear optical microscopic system, Adur *et al.* evaluated details of collagen organization in the dermis in patients with OI. These methods allow differentiation between normal and OI tissue based on collagen density (lower in OI dermis) and autofluorescence index (higher in OI), and they also permit distinction among subtypes of OI.¹²⁵⁶

MARFAN'S SYNDROME

The clinical features of Marfan's syndrome (OMIM 154700) include tall stature, skeletal malformations, arachnodactyly, and dislocation of the lens.^{1257,1258} It is caused by mutations in the fibrillin-1 gene (*FBN1*).¹²⁵⁹ Cutaneous manifestations are relatively insignificant. Marfan's syndrome is discussed further in Chapter 12, page 403.

Histopathology¹⁶

In some cases, thinning of the dermis, resulting from a diminished quantity of collagen and thinner collagen bundles, has been reported. This has been confirmed ultrastructurally. An increase in matrix material and fragmentation of elastic fibers have also been reported.

SYNDROMES OF PREMATURE AGING

The syndromes of premature aging can be a very small or quite large disease group, depending on the criteria used.^{1260,1261} There are five conditions with prominent cutaneous findings that are usually included in any discussion on this subject: Werner's syndrome (adult progeria), progeria (Hutchinson–Gilford syndrome), acrogeria, Rothmund–Thomson syndrome (poikiloderma congenitale), and Cockayne's syndrome.^{1260,1262} The Rothmund–Thomson syndrome includes poikiloderma as a major feature and is accordingly discussed with the lichenoid reaction pattern (see p. 76), whereas in Cockayne's syndrome, photo-

sensitivity and sensitivity of cultured fibroblasts to ultraviolet light is a major feature. The other three syndromes show changes in dermal collagen and accordingly they are considered further in this chapter. In the two types of progeria, this takes the form of sclerodermoid lesions, whereas in acrogeria the dermis is almost always atrophic.

In addition to the five syndromes listed, premature aging is also a feature of Down syndrome.¹²⁶³ The capacity to repair UV-induced DNA damage is diminished in this syndrome, and this deteriorates further with aging.¹²⁶³ The Wiedemann–Rautenstrauch syndrome (OMIM 264090) is a further exceedingly rare progeroid syndrome present at birth.¹²⁶⁴

WERNER'S SYNDROME (ADULT PROGERIA)

Werner's syndrome (OMIM 277700) is a rare, autosomal recessive disorder in which evidence of premature aging becomes manifest between the ages of 15 and 30 years.^{1260,1265} It is common in Japan.¹²⁶⁶ The clinical features include short stature, bird-like facies, juvenile cataracts, a tendency to diabetes mellitus, trophic ulcers of the legs, premature graying of the hair and balding, an increased incidence of neoplasms, and acral sclerodermoid changes.^{1260,1267–1270} Diffuse lentiginosis has been recorded in one case.¹²⁷¹ Extensive tendon calcification and sacroiliitis have been reported in a brother and sister with this syndrome.¹²⁷² Death usually occurs in the fifth decade from the complications of arteriosclerosis.

Skin fibroblasts from patients with Werner's syndrome are difficult to culture, with a slow growth rate and short life span,^{1273,1274} although in one study they produced more collagen but less glycosaminoglycans than normal.¹²⁷⁵ Studies have confirmed that cultured fibroblasts produce increased amounts of some collagen but not type VI;¹²⁷⁶ the levels of types I and III collagen mRNA are increased, suggesting an alteration in the control of collagen synthesis at the transcriptional level.¹²⁷⁷ Fibroblasts appear to become hyporesponsive *in vitro* to a stimulator of collagen synthesis that has been found in the serum of patients with Werner's syndrome.¹²⁷⁸ The pathogenetic significance of these disparate findings remains to be elucidated. Cells in Werner's syndrome may have subtle defects in DNA repair.¹²⁷⁹

It results from mutational inactivation of the human *RECQL2* (helicase) gene found at 8p11–p12.^{1274,1280–1282} It is also known as the *WRN* gene.¹²⁸³ Other conditions resulting from mutations of helicase genes include Bloom's syndrome (see p. 77) and Rothmund–Thomson syndrome (see p. 76).¹²⁸⁰ Chromosomal analyses on cultured fibroblasts reveal that aberrations occur frequently and randomly.¹²⁸⁴

Histopathology

There is usually some epidermal atrophy, although there may be hyperkeratosis over bony prominences.¹²⁶⁷ In the scleroderma-like areas, there is variable hyalinization of the thickened dermal collagen. There may be replacement of subcutaneous fat by connective tissue. The pilosebaceous structures and sweat glands become atrophic. Calcinosis cutis may also develop.¹²⁷⁸

In other areas, the dermis is thinned with a decrease in the size of the collagen bundles^{1278,1285} and degenerative changes in the elastic fibers.

PROGERIA

The Hutchinson–Gilford progeria syndrome (OMIM 176670) is a rare disease with markedly accelerated aging, with clinical features becoming apparent in the first year of life.¹²⁶¹ Its estimated incidence is 1 per 4–8 million live births.¹²⁸⁶ These features include growth retardation, alopecia, craniofacial disproportion, loss of subcutaneous fat, and atrophy of muscle.^{1260,1287–1289} The skin is generally thin as a result of the loss of subcutaneous fat, except for areas with scleroderma-like

plaques.¹²⁹⁰ Acral hyperplastic scars and keloid-like nodules composed of type IV collagen have also been described.¹²⁹¹ Extensive cutaneous calcinosis may develop. To date, mutations in two genes, *LMNA* and *ZMPSTE24*, have been found in this syndrome.¹²⁸⁶ Most reports have implicated the lamin A/C (*LMNA*) gene essential for the synthesis of lamin A from prelamin A. Lamin A is involved in DNA replication, RNA transcription, and other chromatin functions. It is also involved in cell growth and cell death.¹²⁹² The same genes are involved in restrictive dermopathy (see p. 373).¹²⁶¹ A review of the laminopathies resulting from mutations in the *LMNA* gene was published in 2006.¹²⁹³

The biochemical basis of this disease is unknown, but it has been shown that skin fibroblasts are difficult to culture and tropoelastin production by fibroblasts is markedly increased.¹²⁸⁷

Histopathology^{1288,1294}

The scleroderma-like plaques show a diffusely thickened dermis with hyalinization of collagen.¹²⁹⁴ This may assume a homogenized appearance in the lower dermis. Fibrous tissue often extends into the subcutis.¹²⁹⁵ Hair follicles are atrophic and eventually lost.¹²⁹⁶ There are variable changes in the elastic tissue. In other areas of the body, there is loss of subcutaneous fat and some atrophy of the dermis.¹²⁹⁴

ACROGERIA

Acrogeria (Gottron's syndrome) is an exceedingly rare disease (OMIM 201200), with onset in early childhood.¹²⁹⁷ There is atrophy, dryness,

and wrinkling of the skin that is most severe on the face and extremities.^{1260,1262,1297} Interesting associations include bony abnormalities and disorders of dermal elastic tissue in the form of elastosis perforans serpiginosa and perforating elastomas.^{1297–1299} Vascular lesions such as occlusion of the digital arteries and perniosis have been reported in one patient.¹³⁰⁰ Inheritance is probably autosomal recessive. A mutation in the *COL3A1* gene, located at chromosome 2q31–q32, has been reported in several cases.^{1220,1301} A syndrome described as meta-geria has features that overlap with those of acrogeria.^{1260,1262} Acrogeria is regarded by some as a distinct subgroup of type IV Ehlers–Danlos syndrome.¹³⁰²

Histopathology^{1260,1297,1298}

There is atrophy of the dermis with degenerative changes in the collagen. Fibers may be swollen and present a 'boiled' appearance. The subcutaneous fat is often replaced by connective tissue that is indistinguishable from the dermal collagen. Elastic fibers are disrupted and irregular, with some clumping. Changes of elastosis perforans serpiginosa may be present.
